(b) Six sub-optimal G_1/S phase CDK site in Sic1

FIGURE 19-18 Six suboptimal G_1/S phase CDK phosphorylation sites in Sic1 create a switch-like cell cycle entry. (a) A single optimal G_1/S phase CDK site in Sic1 would result in a sluggish G_1 – S phase transition. As G_1/S phase CDKs accumulate during G_1 , Sic1 would get progressively degraded. As a result, S phase CDKs would slowly rise. Instead of an abrupt rise in S phase CDK activity, initiation of S phase would be a drawn-out event. (b) Six suboptimal phosphorylation sites ensure that Sic1 is only fully phosphorylated and hence recognized by the SCF when G_1/S phase CDKs have reached high levels. This also ensures that Sic1 degradation occurs rapidly and when G_1/S phase CDKs have accomplished all their other G_1 tasks. [Adapted from Nash et al., 2001, *Nature* 414:514–521, and D. O. Morgan, 2006.]

Entry into S phase in metazoan cells is regulated in a similar manner as in budding yeast. Like Sic1, the CKI p27 prevents the premature activation of S phase CDKs during G_1 . Unlike Sic1, however, this CKI inhibits both S phase CDKs and G_1/S phase CDKs and has additional cell cycle functions. For example, while inhibiting G_1/S phase CDKs and S phase CDKs, p27 helps assemble and hence activate G_1 CDKs. Similar to the situation in yeast, however, p27 is removed from cyclin-CDK complexes by ubiquitin-dependent protein degradation. Two pathways contribute to p27 degradation. On stimulation with mitogens, mitogen-activated protein kinases phosphorylate p27, promoting its export from the nucleus into the cytoplasm, where one of the cellular ubiquitin ligases, KPC, is found. A second pathway, analogous to the one operating on Sic1, targets p27 for degradation at the G_1 – S phase transition. As G_1/S phase CDKs and S phase CDKs reach high levels during late G_1 and early S phase, they begin to phosphorylate p27, targeting the CKI for ubiquitinylation by SCF. Degradation of p27 causes activation of G_1/S phase and S phase CDKs. These kinases

then initiate S phase by phosphorylating proteins important for the initiation of DNA replication.

Replication at Each Origin Is Initiated Once and Only Once During the Cell Cycle

As discussed in Chapter 4, eukaryotic chromosomes are replicated from multiple replication origins. Initiation of replication from these origins occurs throughout S phase. However, no eukaryotic origin initiates more than once per S phase. Moreover, S phase continues until replication from multiple origins along the length of each chromosome results in complete replication of the entire chromosome. These two factors ensure that the correct gene copy number is maintained as cells proliferate.

S phase CDKs play an essential role in the regulation of DNA replication. The kinases initiate DNA replication only at the G_1 – S phase transition and prevent re-initiation from origins that have already fired. We will first discuss how initiation of DNA replication is controlled and the role of S phase CDKs in the process before turning to the mechanisms whereby these kinases prevent re-initiation.

The mechanisms underlying the initiation of DNA replication are best understood in budding yeast, so we will focus our discussion on this organism. However, it is important to note that the proteins and mechanisms controlling the initiation of DNA synthesis are essentially the same in all eukaryotic species. A protein complex known as the *origin-recognition complex* (ORC) is associated with all DNA replication origins. In budding yeast, replication origins contain an 11-base-pair conserved core sequence to which ORC binds. In multicellular organisms, origins of DNA replication lack a recognizable consensus sequence. Instead, chromatin-associated factors target ORCs to the DNA. ORC and two additional replication initiation factors, Cdc6 and Cdt1, associate with the ORC at origins during G_1 to load the replicative helicases known as the MCM helicase complex onto DNA (Figure 19-19, step 1). The MCM helicases function to unwind the DNA during the initiation of DNA replication.

To ensure that origins fire only once at the beginning of S phase, MCM helicase complex loading and its activation occur at two opposing phosphorylation states. The MCM helicases can only load onto the DNA in a state of low CDK activity that occurs when CDKs are inactivated during exit from mitosis and during early G_1 . In other words, MCM helicases load onto DNA when they are unphosphorylated. In contrast, activation of MCM helicases and the recruitment of DNA polymerases to the unwound origin DNA are triggered by S phase CDKs. Recall that S phase CDKs only become active when G_1/S phase CDK levels reach their peak and CKIs of S phase CDKs are destroyed. It is then that phosphorylation by S phase CDKs and a second heterodimeric protein kinase, DDK, activates the MCM helicase and recruits the polymerases to the sites of replication initiation (Figure 19-19, steps 2 and 3).

So how do S phase CDKs and DDK collaborate to initiate DNA replication? ORC and the two other initiation factors, Cdc6 and Cdt1, recruit the MCM helicases to sites of

FIGURE 19-19 The molecular mechanisms governing the initiation of DNA replication. Step **1**: During exit from mitosis and early G_1 , when CDK activity is low, the MCM loading factors ORC, Cdc6, and Cdt1 load the replicative helicase, the MCM complex, onto origin DNA. Step **2**: Activation of S phase CDKs and DDK mark the onset of S phase. They phosphorylate the MCM helicase, Sld2 and Sld3 (depicted as green phosphorylation events), to facilitate the loading of MCM helicase activators—the Cdc45-Sld3 and the GINS complexes—onto sites of replication initiation. This leads MCM helicases to unwind

DNA. S phase CDKs also prevent reloading of MCM helicases by phosphorylating the pre-RC components Cdc6 and Cdt1 (shown as yellow phosphorylation events), promoting their release from origins and degradation by the SCF. S phase CDKs also phosphorylate MCM helicases, which leads to their export from the nucleus when the helicases disengage from the DNA when replication is complete. Step **3**: DNA polymerases are recruited to origins, which leads to the initiation of DNA synthesis (see Figure 4-31).

replication initiation during G_1 , when CDK activity is low (see Figure 19-19, step **1**). When DDK and S phase CDKs are activated in late G_1 , DDK phosphorylates two subunits of the MCM helicase. The S phase CDKs phosphorylate two proteins called Sld2 and Sld3. These phosphorylation events have an activating effect, promoting the recruitment of MCM helicase activators to sites of replication initiation (the phosphorylation events shown in green in Figure 19-19, steps **2** and **3**). The helicase activators are called the Cdc45-Sld3 complex and the GINS complex. Exactly how they promote activation of the MCM helicases is not yet clear. In addition to activating the MCM helicase to unwind DNA, the Cdc45-Sld3 complex and the GINS complex recruit polymerases to the DNA, polymerase ϵ to synthesize the leading strand and polymerase δ to synthesize the lagging strand (see Figure 19-19, step **3**). The replication machinery then initiates DNA synthesis.

S phase CDKs are not only essential to initiate DNA replication, they are also responsible for ensuring that each origin fires only once during S phase. Preventing re-firing of origins during S phase is brought about by phosphorylation of several components of the MCM helicase loading machinery and the MCM helicase itself. To distinguish these phosphorylation events from the ones required for the initiation of DNA replication, they are depicted in yellow in Figure 19-19. Concomitant with activation of the MCM helicase, Cdc6 and Cdt1 dissociate from the sites of DNA replication initiation. Once they dissociate, their phosphorylation leads to their degradation by the SCF ubiquitin ligase. Phosphorylation of the MCM helicase leads to the export of these proteins from the nucleus after they dissociate from the DNA on completion of DNA replication. Thus only after CDK activity is lowered by APC/C-Cdh1 during exit from mitosis can the MCM helicases be reloaded onto

DNA. As a result, helicase loading is restricted to late stages of mitosis and early G_1 (see Figure 19-19, step 1).

The general mechanisms governing the initiation of DNA replication in metazoan cells parallel those in *S. cerevisiae*, although small differences are found in vertebrates. Phosphorylation of MCM helicase activators by G_1/S phase CDKs and S phase CDKs likely promotes their recruitment to sites of DNA replication initiation. As in yeast, phosphorylation of MCM loading factors likely prevents reloading of MCM helicases until the cell passes through mitosis, thereby ensuring that replication from each origin occurs only once during each cell cycle. In metazoans, a second small protein, geminin, contributes to the inhibition of re-initiation at origins until cells complete a full cell cycle. Geminin is expressed in late G_1 ; it binds to and inhibits MCM helicase loading factors as they are released from origins once DNA replication is initiated during S phase (see Figure 19-19, step 2), contributing to the inhibition of re-initiation at an origin. Geminin contains a destruction box at its N-terminus that is recognized by the APC/C-Cdh1, causing it to be ubiquitinated in late anaphase and degraded by proteasomes. This frees the MCM helicase loading factors, which are also dephosphorylated as CDK activity declines, to bind to ORC on replication origins and load MCM helicases during the following G_1 phase.

Duplicated DNA Strands Become Linked During Replication

During S phase, as chromosomes are duplicated to form sister chromatids, they become tethered to each other by protein links. The linkages between sister chromatids established during S phase will be essential for their accurate segregation during mitosis.

The protein complexes that establish cohesion between sister chromatids are called **cohesins**. The cohesin complex is composed of four subunits: Smc1 (sometimes also called *Rad21*), Smc3, Scc1, and Scc3. Smc1 and Smc3 are members of the SMC protein family, which is characterized by long coiled-coil domains that are flanked by a globular domain containing ATPase activity. The ATPase domains interact with Scc1 and Scc3 and, together, form a ring structure. The structural mechanism by which cohesins link sister chromatids together is not understood, but it is likely that rings of cohesin embrace one or both copies of the replicated DNA. However, it is clear that cohesins are essential to hold the replicated DNA molecules together. When *Xenopus* egg extracts were depleted of cohesin by treatment with antibodies specific for the cohesin SMC proteins, the depleted extracts were able to replicate the DNA in added sperm nuclei, but the resulting sister chromatids did not associate properly with each other.

Some details of how cohesins are loaded onto DNA to mediate sister chromatid cohesion are being unraveled. We know that establishment of cohesion between sister chromatids is tightly tied to DNA replication. Cohesins associate with chromosomes during G_1 (Figure 19-20, step 1). During DNA replication, they are loaded onto chromosomes in such a way that they can hold sister chromatids together. Most

likely this occurs as replication forks replicate the DNA (Figure 19-20, step 2). Converting DNA-bound G_1 cohesins into cohesive complexes requires several cohesin loading factors—including a protein complex related to proteins that load the sliding clamp at the replication fork—and the acetylation of the Smc3 subunit. As we will see in Section 19.6, cohesins are essential to accurately attach the replicated sister chromatids onto the mitotic spindle and for their segregation during mitosis. Cells lacking cohesins or the factors that load them onto chromosomes segregate chromosomes randomly.

KEY CONCEPTS of Section 19.4

Commitment to the Cell Cycle and DNA Replication

- START defines a stage in G_1 after which cells are irreversibly committed to the cell cycle. Molecularly, it is defined as the point when G_1/S phase CDK activity reaches levels sufficient to initiate S phase.
- The molecular events promoting entry into the cell cycle are conserved across species. G_1 CDKs inhibit a transcriptional inhibitor. This allows the transcription of G_1/S phase cyclins and other genes important for S phase.
- Extracellular signals such as nutritional state (in yeast) and the presence of mitogens and anti-mitogens (in vertebrates) regulate entry into the cell cycle.
- Various polypeptide growth factors called mitogens stimulate cultured mammalian cells to proliferate by inducing expression of early-response genes. Many of these encode transcription factors that stimulate expression of delayed response genes encoding the G_1/S phase cyclins and E2F transcription factors.
- The G_1/S phase CDKs phosphorylate and inhibit Cdh1, the specificity factor that directs the anaphase-promoting complex (APC/C) to ubiquitinate S phase and M phase cyclins. This allows S phase cyclins to accumulate in late G_1 .
- In yeast, S phase CDKs initially are inhibited by Sic1. Phosphorylation marks Sic1 for ubiquitination by the SCF ubiquitin-protein ligase and proteosomal degradation, releasing activated S phase CDKs that trigger onset of the S phase (see Figure 19-17).
- DNA replication is initiated from helicase loading sites known as origins of replication.
- Loading and activation of the MCM helicase occur in mutually exclusive cell cycle states: MCM helicase loading can only occur when CDK activity is low (during early G_1); MCM helicases are activated when CDK activity is high.
- S phase CDKs and DDK trigger the initiation of DNA replication by the recruitment of MCM helicase activators to origins (see Figure 19-19).
- Initiation of DNA replication occurs at each origin only once during the cell cycle. This is achieved because S phase CDKs activate the helicases and at the same time prevent additional helicases from loading onto DNA.

FIGURE 19-20 Model for establishing cohesin linkage of sister chromatids. There is strong evidence that the cohesin complex is circular, but it is not known whether a single cohesin ring links sister chromatids or whether two rings, one each around the separate sister chromatids, are linked to each other like links in a chain. For simplicity, only one ring is shown here. Step 1: Cohesins are loaded onto chromosomes during G₁, but they do not possess cohesive properties (indicated as cohesins laterally associated with chromosomes). Step 2: Concomitant with DNA replication, and most likely closely behind the replication fork, cohesins are converted into cohesive molecules, able to hold sister chromatids together (indicated as cohesin rings

encircling the replicated sister chromatids). This conversion into cohesive cohesins requires cohesin loading factors. During G₂, sister chromatids are replicated and linked along their entire length by cohesins. During this time, the Mei-S332/Sgo proteins recruit the protein phosphatase 2A (PP2A) to centromeric regions. Step 3: In vertebrate cells, cohesins are released from chromosome arms during prophase and early metaphase by the action of Polo kinase and Aurora B kinase. By the end of metaphase, cohesins are retained only in the region of the centromere, where PP2A prevents cohesin phosphorylation and hence dissociation through recruiting PP2A.

- Cohesins establish linkages between the replicated DNA molecules. This linking mechanism is coupled to DNA replication.

19.5 Entry into Mitosis

Once S phase has been completed and the entire genome has been duplicated, the pairs of duplicated DNA chromosomes—the sister chromatids—are segregated to the future daughter cells. This process requires not only the formation of the apparatus that facilitates this segregation—the mitotic spindle—but essentially a complete remodeling of the cell. Chromosomes condense and attach to the mitotic spindle, the nuclear envelope is disassembled, and almost all organelles are rebuilt or modified. All these events are triggered by mitotic CDKs. This section will first discuss how the mitotic CDKs are precipitously activated after the completion of DNA replication, during G₂. We will then see how these pro-

tein kinases bring about the dramatic changes in the cell necessary to facilitate sister chromatid segregation during anaphase, focusing on the events as they occur in metazoans.

Precipitous Activation of Mitotic CDKs Initiates Mitosis

Mitotic CDKs initiate mitosis. Whereas levels of the catalytic CDK subunit are constant throughout the cell cycle, mitotic cyclins gradually accumulate during S phase. Most eukaryotes contain multiple mitotic cyclins, which for historical reasons are called cyclin A and cyclin B. As they assemble, mitotic CDK complexes are maintained in an inactive state through inhibitory phosphorylation on the CDK subunit. Recall from Section 19-3 that two highly conserved tyrosine and threonine residues in mammalian CDKs are subject to regulated phosphorylation. In CDK1, the mitotic CDK, phosphorylation of tyrosine 15 and threonine 14 maintains mitotic cyclin-CDK complexes in an inactivate state. The phosphorylation state of T14 and Y15 is controlled by a dual-specificity protein kinase

FIGURE 19-21 Phosphorylation on the CDK subunit restrains mitotic CDK activity during S phase and G₂. Mitotic cyclins are synthesized during S phase and G₂ and bind to CDK1. However, the cyclin-CDK complex is not active because threonine 14 and tyrosine 15 of the CDK1 subunit are phosphorylated by the protein kinase Wee1. Once DNA replication has been completed, the protein phosphatase Cdc25 is activated, and the phosphatase dephosphorylates CDK1. Active mitotic CDKs further stimulate Cdc25. At the same time, mitotic CDKs inhibit Wee1, the protein kinase that places the inhibitory phosphorylation on the CDK subunit. Ongoing DNA replication inhibits Cdc25 activity. How Cdc25 is initially activated upon completion of DNA replication to put in motion these feedback loops is not yet known.

known as Wee1 and a dual-specificity phosphatase Cdc25 (Figure 19-21). The regulation of mitotic CDKs by these activities underlies the abrupt activation of their kinase activity at the G₂-M phase transition and explains the observation that although mitotic cyclins gradually accumulate during S phase and G₂, mitotic CDKs are not active until cells enter mitosis.

Studies in the fission yeast *Schizosaccharomyces pombe* unraveled the mechanisms that lead to the precipitous activation of mitotic CDKs during G₂. The dual-specificity protein kinase Wee1 phosphorylates CDKs on the inhibitory tyrosine 15. (Threonine 14 is not phosphorylated in *S. pombe* CDK1.) Yeast cells with a defective *wee1*⁺ gene activate mitotic CDKs prematurely and hence experience premature entry into mitosis. Wee1 mutants not only enter mitosis prematurely but are also smaller. This is because unlike most other eukaryotes, which coordinate cell size and cell division during G₁, this coordination occurs during G₂ in fission yeast. Fission yeast cells carrying a mutant CDK1 gene in which the tyrosine 15 residue is replaced by phenylalanine (phenylalanine is structurally similar to tyrosine but cannot be phosphorylated) show the same premature mitotic CDK activation and entry into mitosis. The phosphatase that opposes Wee1 is Cdc25. Fission yeast cells carrying mutations in the *cdc25*⁺ gene arrest in G₂, indicating that the phosphatase is essential for entry into mitosis.

Vertebrates contain multiple Wee1 protein kinases and multiple Cdc25 phosphatases that collaborate to control not only mitotic CDK activity but also the activity of G₁/S phase CDKs. One member of the Cdc25 family of phosphatases, Cdc25A, is activated in late G₁. It removes the inhibitory phosphorylation on tyrosine 15 of the G₁/S phase CDKs and S phase CDK catalytic subunit to activate the kinases. Another family member, Cdc25C, is active during G₂ and removes the inhibitory phosphorylation on mitotic CDKs.

Activation of mitotic CDKs is the consequence of rapid inactivation of Wee1 and activation of Cdc25. Central to this rapid transition are feedback loops, where mitotic CDKs activate Cdc25 and inactivate Wee1 (see Figure 19-21). Phosphorylation of Cdc25 by mitotic CDKs stimulates its phosphatase activity; phosphorylation of Wee1 by mitotic CDKs inhibits its kinase activity. Ongoing DNA replication inhibits Cdc25 activity. A critical question that we know little about is how this positive feedback loop is started once DNA replication has been completed. CDKs that function earlier in the cell cycle have been suggested to start the positive feedback loop.

Although it is not yet known how the precipitous activation of mitotic CDKs is initiated, it is clear that once active, these protein kinases set in motion all the events necessary to ready the cell for chromosome segregation. The activation of mitotic CDKs is associated with changes in the subcellular localization of these kinases. Mitotic CDKs initially associate with centrosomes, where they are thought to facilitate centrosome maturation. They then enter the nucleus, where they bring about chromosome condensation and nuclear envelope breakdown. In what follows we will discuss how the mitotic CDKs accomplish the coordinated execution of mitosis.

During DNA replication initiation, S phase CDKs work together with DDK to promote MCM helicase activation. As in the initiation of DNA replication, CDKs collaborate with other protein kinases to bring about the mitotic events. The Polo kinase family is critical for formation of the mitotic spindle as well as chromosome segregation. The family of Aurora kinases plays key roles in mitotic spindle formation and ensuring that chromosomes attach to the mitotic spindle in the correct way so that they are segregated accurately during mitosis. Their contribution to the various mitotic events will also be discussed.

Mitotic CDKs Promote Nuclear Envelope Breakdown

During interphase, chromosomes are surrounded by the nuclear envelope. The centrosomes that form the mitotic spindle are located in the cytoplasm. For chromosomes to interact with the microtubules nucleated by the centrosomes, the nuclear envelope needs to be dismantled.

The nuclear envelope is a double-membrane extension of the endoplasmic reticulum containing many nuclear pore complexes (see Figures 9-32 and 13-33). The lipid bilayer of the inner nuclear membrane is associated with the nuclear lamina, a meshwork of lamin filaments adjacent to the inside face of the nuclear envelope (Figure 19-22a). The three nuclear lamins (A, B, and C) present in vertebrate cells be-

FIGURE 19-22 The nuclear lamina and its regulation by phosphorylation. (a) Electron micrograph of the nuclear lamina from a *Xenopus* oocyte. Note the regular mesh-like network of lamin intermediate filaments. This structure lies adjacent to the inner nuclear membrane (see Figure 18-46). (b) Schematic diagrams of the structure of the nuclear lamina. Two perpendicular sets of 10-nm-diameter filaments built of lamins A, B, and C form the nuclear lamina (top). Individual lamin filaments are formed by end-to-end polymerization of lamin tetramers, which consist of two lamin coiled-coil dimers (middle). The red and blue circles represent the globular N-terminal and C-terminal domains, respectively. Phosphorylation of specific serine residues near the ends of the rod-like central section of lamin dimers causes the tetramers to depolymerize (bottom). As a result, the nuclear lamina disintegrates. [Part (a) from U. Aebi et al., 1986, *Nature* **323**:560; courtesy of U. Aebi; part (b) adapted from A. Murray and T. Hunt, 1993, *The Cell Cycle: An Introduction*, W. H. Freeman and Company.]

long to a class of cytoskeletal proteins, the intermediate filaments, that are critical in supporting cellular membranes. Lamins A and C, which are encoded by the same transcription unit and produced by alternative splicing of a single pre-mRNA, are identical except for a 133-residue region at the C-terminus of lamin A, which is absent in lamin C. Lamin B, encoded by a different transcription unit, is modified post-transcriptionally by the addition of a hydrophobic isoprenyl group near its carboxyl terminus. This fatty acid becomes embedded in the inner nuclear membrane, thereby anchoring the nuclear lamina to the membrane (see Figure 10-19). All three nuclear lamins form dimers containing a rod-like α -helical coiled-coil central section and globular head and tail domains; polymerization of these dimers through head-to-head and tail-to-tail associations generates the intermediate filaments that compose the nuclear lamina (Figure 19-22b).

Once mitotic CDKs are activated at the end of G_2 , they phosphorylate specific serine residues in all three nuclear lamins. This causes depolymerization of the lamin intermediate filaments (see Figure 19-22b). The phosphorylated lamin A and C dimers are released into solution, whereas the phosphorylated lamin B dimers remain associated with the nuclear membrane via their isoprenyl anchor. Depolymerization of the nuclear lamins leads to disintegration of the nuclear lamina meshwork and contributes to disassembly of the nuclear envelope.

Mitotic CDKs also affect other nuclear envelope components (Figure 19-23). The CDKs phosphorylate specific **nucleoporins**, which causes nuclear pore complexes to dissociate into subcomplexes during prophase. Phosphorylation of integral membrane proteins of the inner nuclear membrane is thought to decrease their affinity for chromatin and further contributes to the disassembly of the nuclear envelope. The weakening of the associations between the inner nuclear membrane proteins and the nuclear lamina and chromatin allows sheets of inner nuclear membrane to retract into the endoplasmic reticulum, which is continuous with the outer nuclear membrane.

Mitotic CDKs Promote Mitotic Spindle Formation

A key function of mitotic CDKs is to induce the formation of the mitotic spindle, also known as the mitotic apparatus. As we saw in Chapter 18, the mitotic spindle is made of microtubules that attach to chromosomes via specialized protein structures associated with chromosomes known as **kinetochores**. In most organisms, the mitotic spindle is organized by **centrosomes**, sometimes called **spindle pole bodies**. They contain a specialized tubulin, γ tubulin, which together with associated proteins nucleates microtubules. Notable exceptions to centrosome-based spindle assembly mechanisms are higher plants and metazoan oocytes. In these cells, (–) ends of microtubules are cross-linked and the microtubules self-assemble into a spindle.

The function of the mitotic spindle is to segregate chromosomes so that the sister chromatids separate from each other and are moved to opposite poles of the mitotic spindle (see Figure 18-37). To achieve this, chromosomes have to attach to the

FIGURE 19-23 Nuclear envelope proteins phosphorylated by mitotic CDKs. Step 1: Components of the nuclear pore complex (NPC) are phosphorylated by mitotic CDKs in prophase, causing NPCs to dissociate into soluble and membrane-associated NPC subcomplexes. Step 2: Mitotic CDK phosphorylation of inner nuclear membrane (INM) proteins inhibits their interactions with the nuclear lamina and chromatin. Step 3: Mitotic CDK phosphorylation of nuclear lamins causes their depolymerization and dissolution of the nuclear lamina. Step 4: Mitotic CDK phosphorylation of chromatin proteins induces chromatin condensation and inhibits interactions between chromatin and the nuclear envelope. [Adapted from B. Burke and J. Ellenberg, 2002, *Nat. Rev. Mol. Cell Biol.* 3:487.]

mitotic spindle so that one kinetochore of each sister chromatid pair attaches to microtubules emanating from opposite poles. Sister chromatids are then said to be **bi-oriented**. In what follows, we will discuss how the mitotic spindle forms, how chromosomes attach to it, and how cells correct faulty attachments.

During G_1 , cells contain a single centrosome that functions as the major microtubule nucleating center of the cell.

Mitotic spindle formation begins at the G_1 -S phase transition with the duplication of centrosomes. The mechanism whereby this duplication occurs is poorly understood, but at the heart of this process is the duplication of the pair of **centrioles**, short microtubules arranged orthogonally to each other. As discussed in Chapter 18, G_1 cells contain a single pair of centrioles. Concomitant with entry into S phase and triggered by the G_1 /S phase CDKs, the two centrioles split apart, and each centriole begins to grow a daughter centriole (see Figure 18-35). The new centrioles grow and mature during S phase, each centriole pair begins to assemble centrosomal material, and by G_2 the two centrosomes have formed. Several additional protein kinases have been identified that control centrosome duplication. Chief among them is a member of the conserved Polo kinase family, Plk4. How G_1 /S phase CDKs and Plk4 promote centrosome duplication is not yet understood but is thought to involve the phosphorylation of multiple centrosome components, which facilitates their duplication and growth. As we will see, the Polo kinases not only play a key role in centrosome duplication but also participate in essentially all aspects of mitosis.

The key initiating step of mitotic spindle formation is the severing of the ties that link the duplicated centrosomes. This **centrosome disjunction** occurs in G_2 and is triggered by mitotic CDKs (see Figure 18-35). As soon as this separation occurs, microtubules are nucleated from both centrosomes and they move away from each other, pulled by the motor protein dynein. The specifics of microtubule array formation and mitotic spindle assembly were discussed in Chapter 18. Here we will briefly consider how chromosomes attach to the mitotic spindle and how mistakes in the process are corrected.

For chromosomes to be accurately segregated during mitosis, the sister chromatid pair has to be stably bi-oriented on the mitotic spindle (Figure 19-24). How is this accomplished? Once centrosomes have moved apart from each other, microtubules, in a search-and-capture mechanism, begin to interact with kinetochores of sister chromatid pairs. Initially, chromosomes glide along the length of microtubules propelled by motor proteins. When the chromosome reaches the end of a

VIDEO: Normal Cell Division in *C. elegans* Embryogenesis

FIGURE 19-24 Chromosome attachment to the mitotic spindle. Chromosomes attach to the mitotic spindle and congress to the spindle center. They then attach via their kinetochores to the ends of microtubules (called end-on attachments), and these attachments are stabilized by additional microtubules. The final chromosome attachment where the chromosome has stably bi-oriented on the mitotic spindle is shown.

FIGURE 19-25 Stable and unstable chromosome attachments.

When sister kinetochores attach to microtubules emanating from opposite spindle poles, they are stably attached. This configuration is called **amphitelic attachment** (a). Microtubules (green) pull kinetochores (tan); cohesins resist this pulling force. This leads to kinetochores being pulled away from the protein kinase Aurora B (red zone), which localizes to the inter sister kinetochore space. As a result, Aurora B can no longer phosphorylate the microtubule binding factors at the kinetochore and kinetochore-microtubule attachments are stable. When one kinetochore attaches to microtubules emanating from two opposite spindle poles (merotelic attachment, b), or both sister kinetochores attach to microtubules emanating from the same spindle pole (syntelic attachment, c), or only one of the two sister kinetochores attaches to microtubules (monotelic attachment, d), kinetochores are not pulled out of the Aurora B zone. As a result, Aurora B phosphorylates the microtubule binding subunits of the kinetochore and microtubule attachments are destabilized.

microtubule, the kinetochores attach to microtubules in an end-on attachment, the final configuration in which chromosomes are linked to the mitotic spindle. Kinetochore of sister chromatids then bind microtubules emanating from the opposite spindle pole. In the end, the sister chromatid pair is said to be stably bi-oriented on the mitotic spindle.

The ultimate goal of chromosome attachment to the mitotic spindle is that each and every chromosome is attached to the mitotic spindle in a bi-oriented manner (also known as **amphitelic attachment**; Figure 19-25a). How does the cell “know” that this has occurred? Microscopic analysis of chromosome attachment has shown that initially many chromosomes attach to microtubules in faulty ways. A kinetochore can attach to microtubules emanating from both poles, a situation called **merotelic attachment** (Figure 19-25b). Kinetochore of a sister chromatid pair can attach to microtubules from the same pole (**syntelic attachment**; Figure 19-25c) or only one kinetochore can attach to microtubules (**monotelic attachment**; Figure 19-25d). Clearly, none of these attachments are productive in the sense that they would not result in accurate chromosome segregation. Thus mechanisms must be in place that detect and correct such faulty attachments.

The sensing mechanism used by cells to detect incorrect attachments is based on tension. When sister chromatids are correctly attached to microtubules, their kinetochores are under tension (see Figure 19-25a). Microtubules attached to the kinetochores pull at them and the cohesin molecules that hold the sister chromatids together withstand these forces, creating tension at kinetochores. Merotelic, syntelic, or monotelic attachment leads to insufficient tension at kinetochores, allowing the cell to distinguish these faulty forms of attachment from the correct amphitelic one.

How does the cell sense whether or not kinetochores are under tension? The protein kinase **Aurora B** and its associated regulatory factors, together known as the chromosomal passenger complex (CPC), sense kinetochores that are not under tension and sever these microtubule attachments, giving cells a

second chance to get the attachment right. The molecular basis for this sensing mechanism is partly understood. Aurora B phosphorylates a number of kinetochore components involved in microtubule binding. When phosphorylated, these proteins lose their microtubule-binding activity. Aurora B localizes to the region of sister chromatids *between* the two kinetochores. When kinetochores are not under tension, they are in close proximity to Aurora B and the protein kinase can phosphorylate the microtubule-binding subunits of the kinetochores, destabilizing any kinetochore-microtubule attachments (see Figure 19-25b–d). When microtubules are attached correctly to kinetochores, microtubule forces pull kinetochores away from Aurora B and the kinase can no longer reach its targets at kinetochores (see Figure 19-25a).

Microtubules continuously pull on chromosomes. Once all chromosomes have attached to microtubules in an amphitelic manner, the only things that prevent chromosomes from segregating to the poles and that hold them back in the middle of the spindle are the cohesin complexes (see Figure 19-25a). As we will see in Section 19.6, it is the severing of these cohesin molecules that initiates anaphase chromosome segregation.

Chromosome Condensation Facilitates Chromosome Segregation

Chromosome segregation not only requires the building of the apparatus that segregates chromosomes, it also requires that the DNA is compacted into travel-friendly structures. An attempt to segregate the long and intertwined DNA-protein complexes present in interphase cells would lead to breakage of the DNA and hence loss of genetic material. To

FIGURE 19-26 Scanning electron micrograph of a metaphase chromosome. During metaphase, the chromosomes are fully condensed and the two individual sister chromatids are visible. [Biophoto Associates/Photo Researchers.]

avoid this fate, cells compact their chromosomes during prophase into the dense structures we have become acquainted with through light or electron microscopy (Figure 19-26).

Chromosome condensation results in a dramatic reduction in chromosome length, up to 10,000-fold in vertebrates. The second key aspect of the compaction process is the untangling of the intertwined sister chromatids. This process is called **sister chromatid resolution** and is mediated in part by the decatenation activity of topoisomerase II and goes hand in hand with the condensation process.

Condensation of chromosomes is not very well understood, but central to the process is a protein complex known as the **condensin complex**. This protein complex is related to the cohesin complex that links sister chromatids together after DNA replication and was first identified based on its ability to promote chromosome condensation in frog extracts. Like the cohesin complex, condensins are composed of two large coiled-coil SMC protein subunits that associate through their ATPase domains with non-SMC subunits. When condensin function is lost in cells, chromosomes do not condense and sister chromatid tangles are not resolved. How condensins compact chromosomes is not understood, but in analogy to cohesin rings, condensins may create intrachromosomal linkages that package chromosomes into the characteristic loops seen in electron micrographs of compacted chromosomes.

Like all early mitotic events, chromosome condensation is ultimately triggered by mitotic CDKs. The exact mechanisms whereby these kinases induce chromosome condensation is not

known, but it appears that mitotic CDKs induce the process at least in part through activating condensins. Two of the non-SMC condensin subunits are targets of mitotic CDKs. Their phosphorylation stimulates condensins to supercoil DNA *in vitro*.

Finally, processes acting in parallel to condensins also contribute to chromosome compaction. The dissociation of cohesins from chromosomes is such a parallel process. A large fraction of cohesins is removed from chromosomes during prophase (see Figure 19-20, step 3). This process is mediated by phosphorylation of cohesins by Polo kinase and Aurora B kinase. In most organisms, cohesins are only maintained around centromeres. Cohesins around centromeres are protected from phosphorylation-dependent removal by protein phosphatase 2A (PP2A). This phosphatase is recruited to centromeric regions by a member of a family of PP2A targeting factors known as the Mei-S332/Shugoshin family of proteins. The protected pool of cohesins provides the resistance to the pulling force exerted by microtubules necessary to establish tension at bi-oriented kinetochores. As we will see in Section 19.8, this protection mechanism also plays an essential role in establishing the meiotic chromosome segregation pattern.

KEY CONCEPTS of Section 19.5

Entry into Mitosis

- Mitotic CDKs induce entry into mitosis in all eukaryotes.
- Mitotic CDKs are held inactive until the completion of DNA replication by inhibitory phosphorylation on the CDK subunit.
- Mitotic CDKs promote their own activation through positive feedback loops leading to the rapid inactivation of Wee1 kinase and activation of Cdc25 phosphatase.
- Mitotic CDKs induce nuclear envelope breakdown in most eukaryotes by phosphorylating lamins.
- Centrosome duplication occurs during S phase. Mitotic CDKs induce the separation of the duplicated centrosomes, which initiates mitotic spindle formation.
- Sister chromatids attach to the mitotic spindle via their kinetochores in a bi-oriented manner, with one sister kinetochore attaching to microtubules emanating from one spindle pole and the other one to microtubules nucleated by the other spindle pole.
- Cells sense bi-orientation of sister chromatids through a tension-based mechanism. When kinetochores are not under tension, the protein kinase Aurora B phosphorylates the microtubule binding subunits of the kinetochore, which decreases their microtubule binding affinity.
- Chromosomes must be compacted for segregation.
- Condensins, protein complexes that are related to cohesins, facilitate chromosome condensation and are activated by mitotic CDKs.

19.6 Completion of Mitosis: Chromosome Segregation and Exit from Mitosis

Once all chromosomes have condensed and correctly attached to the mitotic spindle, chromosome segregation commences. In this section, we will discuss how cleavage of cohesins by a protease known as separase triggers anaphase chromosome movement and how this cleavage is regulated. We will then explore how the machinery that initiates cohesin cleavage at the metaphase-anaphase transition, the APC/C, also initiates mitotic CDK inactivation. Next, we will see how phosphatases activated at the end of mitosis participate in mitotic CDK inactivation, bringing about the disassembly of mitotic structures and the resetting of the cell to the G_1 state. We will end this section with a discussion of cytokinesis, the process that produces two daughter cells.

Separase-Mediated Cleavage of Cohesins Initiates Chromosome Segregation

As mentioned in the previous section, each sister chromatid of a metaphase chromosome is attached to microtubules via its kinetochore (see Figure 19-24). At metaphase, the spindle is in a state of tension, with forces pulling the two kinetochores toward the opposite spindle poles. Sister chromatids do not separate because they are held together at their centromeres by cohesin complexes. In all organisms analyzed to date, loss of cohesins from chromosomes triggers anaphase chromosome movement. The mechanism that brings about this loss of cohesins from chromosomes is conserved too. A protease known as **separase** cleaves a subunit of cohesin called Scc1 or Rad21, breaking the protein circles linking sister chromatids (Figure 19-27). Once this link is broken, anaphase begins as poleward force exerted on kinetochores moves the split sister chromatids toward spindle poles.

Cohesin cleavage was discovered in budding yeast. Analysis of the Scc1 subunit by Western blot analysis showed that the protein migrated in SDS PAGE gels according to its predicted molecular weight from G_1 until metaphase, but during anaphase the protein ran considerably faster in SDS PAGE, indicating the protein became somehow smaller. Subsequent studies showed that the faster-migrating form of Scc1 was indeed a cleavage product. Insight into the identity of the protein that was responsible for the cleavage of cohesin came from the analysis of previously identified yeast mutants that failed to segregate chromosomes during anaphase. A mutant in the gene encoding *ESP1*—what we now know to be separase—failed to produce the cleavage fragment. Subsequent analyses revealed not only that separase is a protease but that cleavage of cohesin is essential for chromosome segregation. Cells expressing a form of Scc1 with its cleavage sites mutated fail to segregate their chromosomes. Given the irreversible nature of Scc1 cleavage, it is absolutely essential that separase activity is tightly controlled. In what follows we will discuss this regulation.

The APC/C Activates Separase Through Securin Ubiquitylation

Prior to anaphase, a protein known as **securin** binds to and inhibits separase (see Figure 19-27). Once all kinetochores have attached to spindle microtubules in the correct bi-oriented manner, the APC/C ubiquitin ligase directed by specificity factor Cdc20 ubiquitinylates securin (note that this specificity factor is distinct from Cdh1, which targets APC/C substrates for degradation later during mitosis). Polyubiquitylated securin is rapidly degraded by proteasomes, thereby releasing separase.

APC/C^{Cdc20} is activated in prophase by mitotic CDK phosphorylation of several APC/C subunits. However, this

FIGURE 19-27 Regulation of cohesin cleavage. Separase, a protease that can cleave the Scc1 subunit of cohesin complexes, is inhibited before anaphase by the binding of securin. Mitotic CDKs also inhibit separase by phosphorylating it. When all the kinetochores have attached to spindle microtubules and the spindle apparatus is properly assembled and oriented, the Cdc20 specificity factor associated with

the APC/C directs it to ubiquitylate securin and mitotic cyclins. Following securin degradation and a decrease in mitotic CDK activity, the released and dephosphorylated separase cleaves the Scc1 subunit, breaking the cohesin circles and allowing sister chromatids to be pulled apart by the spindle apparatus that is pulling them toward opposite spindle poles.

phosphorylated APC/C^{Cdc20} is not active until all chromosomes have bi-oriented on the mitotic spindle. As we will see in Section 19.7, APC/C^{Cdc20} is inhibited by a checkpoint pathway that ensures that mitosis does not continue until all chromosomes have achieved proper attachment to the mitotic apparatus. Cdc20 is inhibited until every kinetochore has attached to microtubules and tension is applied to the kinetochores of all sister chromatids, pulling them toward opposite spindle poles. In vertebrate cells, separase is also regulated by phosphorylation. Mitotic CDK activity inhibits separase during prophase and metaphase. Only when mitotic CDK activity begins to decline at the metaphase-anaphase transition through APC/C^{Cdc20}-mediated protein degradation can separase become active and trigger chromosome segregation.

Once cohesins are cleaved, anaphase chromosome movement ensues. As discussed in Chapter 18, chromosome segregation is mediated by microtubule depolymerization and motor proteins as spindle poles move away from each other. Decline in mitotic CDK activity is important for these anaphase chromosome movements. When mitotic CDK inactivation is inhibited, anaphase does occur, but it is abnormal. Dephosphorylation of a number of microtubule-associated proteins that affect microtubule dynamics appears important for this process. In budding yeast, this dephosphorylation is brought about by the protein phosphatase Cdc14, which we will see, plays an essential role in the final cell cycle stage, exit from mitosis.

Mitotic CDK Inactivation Triggers Exit from Mitosis

Anaphase spindle elongation and the events associated with exit from mitosis—mitotic spindle disassembly, chromosome decondensation, and nuclear envelope re-formation—are brought about by the dephosphorylation of CDK substrates. In other words, exit from mitosis can be viewed as a reversal of entry into mitosis. The phosphorylation events that triggered the different mitotic events need to be undone for the cell to reverse to the G₁ state.

Dephosphorylation of mitotic CDK substrates is caused by the inactivation of mitotic CDKs. In most organisms, mitotic CDK inactivation is triggered by APC/C^{Cdc20}-mediated degradation of mitotic cyclins. As mitotic CDKs activate APC/C^{Cdc20}, they initiate their own demise. In budding yeast only about 50 percent of mitotic cyclins are degraded by APC/C^{Cdc20}. As we will see in Section 19.7, a pool of mitotic cyclins is protected from APC/C^{Cdc20} to allow for enough time to position the mitotic spindle accurately within the cell. How a fraction of mitotic cyclins is protected from APC/C^{Cdc20} is not known, but it is clear that a second mitotic CDK-inactivating step is needed for exit from mitosis to occur. The conserved protein phosphatase Cdc14 brings about this second step in mitotic CDK inhibition.

In budding yeast, complete inactivation of mitotic CDKs requires the destruction of mitotic cyclins by APC/C^{Cdh1} and the accumulation of the CDK inhibitor Sic1, which—recall—holds S phase CDKs in check until cells enter the cell cycle. Both APC/C^{Cdh1} and Sic1 are inhibited by mitotic

FIGURE 19-28 The protein phosphatase Cdc14 triggers exit from mitosis in budding yeast. During mitosis, mitotic CDK activity inhibits its inhibitors, APC/C^{Cdh1} and Sic1. During G₁, APC/C^{Cdh1} and Sic1 inhibit mitotic CDKs. During exit from mitosis, the protein phosphatase Cdc14 throws the switch between these two antagonistic states. The mitotic exit network activates the phosphatase during anaphase, allowing it to dephosphorylate APC/C^{Cdh1}, thereby activating it. The phosphatase also promotes the accumulation of Sic1. In addition, Cdc14 dephosphorylates the many mitotic CDK substrates, which leads to rapid exit from mitosis.

CDKs. Conversely, APC/C^{Cdh1} and Sic1 inhibit mitotic CDKs (Figure 19-28). The protein phosphatase Cdc14 throws the switch between these two mutually antagonistic states during anaphase. Cdc14 is kept inactive during most of the cell cycle, but the phosphatase is activated during anaphase by a GTPase signaling pathway known as the mitotic exit network (MEN). This signaling cascade is, as we will see in Section 19.7, responsive to spindle position and only becomes active in anaphase, when the anaphase spindle is properly positioned within the cell. Once activated during anaphase, Cdc14 dephosphorylates APC/C^{Cdh1} and Sic1 to promote mitotic cyclin degradation and mitotic CDK inactivation, respectively. This leads to exit from mitosis.

Phosphatase activity is also essential for exit from mitosis in vertebrates. Simple inactivation of mitotic CDKs is not sufficient to trigger the timely exit from mitosis. It is not yet clear which phosphatase dephosphorylates CDK substrates to reset the cell to the G₁ stage. Both protein phosphatase 1 and protein phosphatase 2A have been implicated in the process.

Ultimately, reversal of mitotic CDK phosphorylation changes the activities of many proteins back to their interphase state. Dephosphorylation of condensins, histone H1, and other chromatin-associated proteins leads to the decondensation of mitotic chromosomes in telophase. The targets of CDKs whose dephosphorylation is important for mitotic spindle disassembly are not known, but likely multiple proteins are targets. More is known about how the nuclear envelope reforms. Dephosphorylated inner nuclear membrane proteins are thought to bind to chromatin once again. As a result, multiple projections of regions of the ER membrane containing these proteins are thought to associate with the surface of the decondensing chromosomes and then fuse with one another directed by an unknown mechanism to form a continuous double membrane around each chromosome (Figure 19-29). Dephosphorylation of nuclear pore subcomplexes allows them to reassemble into complete NPCs traversing the inner and outer membranes soon after fusion of the ER projections. Ran-GTP, required for driving most nuclear import and

VIDEO: Nuclear Envelope Dynamics During Mitosis

FIGURE 19-29 Model for reassembly of the nuclear envelope during telophase. Extensions of the endoplasmic reticulum (ER) associate with each decondensing chromosome and then fuse with one another, forming a double membrane around the chromosome. Dephosphorylated nuclear pore subcomplexes reassemble into nuclear pores, forming individual mini-nuclei called *karyomeres*. The enclosed chromosome further decondenses, and subsequent fusion of the nuclear envelopes of all the karyomeres at each spindle pole forms a single nucleus containing a full set of chromosomes. NPC, nuclear pore complex. [Adapted from B. Burke and J. Ellenberg, 2002, *Nature Rev. Mol. Cell Biol.* 3:487.]

export (see Chapter 13), stimulates both fusion of the ER projections to form daughter nuclear envelopes and assembly of NPCs (see Figure 19-29). The Ran-GTP concentration is highest in the microvicinity of the decondensing chromosomes because the Ran-guanine nucleotide-exchange factor (Ran-GEF) is bound to chromatin. Consequently, membrane fusion is stimulated at the surfaces of decondensing chromosomes, forming sheets of nuclear membrane with inserted NPCs.

Cytokinesis Creates Two Daughter Cells

When chromosome segregation is completed, the cytoplasm and organelles are distributed between the two future daughter cells. This process is called **cytokinesis**. With the exception of higher plants, the division of the cell is brought about by a **contractile ring** made of actin and the actin motor myosin (see Figure 17-36). During cytokinesis, the ring contracts in a manner similar to muscle contraction, pulling the membrane inward and eventually closing the connection between the two daughter cells.

Cytokinesis must be coordinated with other cell cycle events in space and time. For cell division to produce two daughter cells each containing the components necessary for survival, the division plane must be placed so that each cell receives approximately half of the mother cell's cytoplasmic content and *exactly* half of the genetic content. Cytokinesis must also be coordinated with the temporal sequence of cell cycle events, the completion of mitosis. In what follows, we will explore both these aspects of cytokinesis regulation.

In animal cells, the contractile ring forms during anaphase and is placed in the middle of the anaphase spindle. This ensures that each daughter cell receives half of the genetic material. Despite the importance of this coordination, surprisingly little is known about it. Some experiments support the idea that signals sent from the **spindle midzone** to the cell cortex are important to coordinate the site of cytokinesis with spindle position. Other research suggests that microtubules of the spindle interact with the cell cortex, positioning the **cleavage furrow** with respect to spindle pole position. Most likely, a combination of these pathways governs the formation of the cleavage furrow during cytokinesis.

In budding yeast and fission yeast, the site of cytokinesis is determined prior to mitosis. In budding yeast, this occurs during G_1 , when the bud site is determined. In fission yeast, proteins important for contractile ring formation accumulate in the middle of the cell during G_2 . Irrespective of the sequence of events—site of mitosis first, then site of cytokinesis or vice versa—it is clear that these events must be tightly coordinated. As we will see in Section 19.7, cells have developed surveillance mechanisms that ensure that the site of cytokinesis is coordinated with spindle position. This is especially important during **asymmetric cell divisions**, which give rise to cells of different size and/or fate. Such cell divisions are essential during development and in stem cell divisions (see Chapter 21). Cytokinesis must also be coordinated with other cell cycle events. The major signal for cytokinesis is the inactivation of mitotic CDKs. Cells expressing a stabilized version of mitotic cyclins progress through anaphase but do not undergo cytokinesis. The CDK targets in the cytokinesis machinery have not yet been discovered.

This concludes our discussion of the molecular events of cell division. As we saw, cyclin-dependent kinases and ubiquitin-mediated protein degradation are at the center of this control (Figure 19-30). In what follows, we will discuss the mechanisms that ensure a subsequent cell cycle stage is not initiated until the previous has been completed and that each cell cycle step occurs accurately.

FIGURE 19-30 Fundamental processes in the eukaryotic cell cycle. See text for discussion.

KEY CONCEPTS of Section 19.6

Completion of Mitosis: Chromosome Segregation and Exit from Mitosis

- Cleavage of cohesin by separase induces chromosome segregation during anaphase.
- At the onset of anaphase, the APC/C is directed by Cdc20 to ubiquitinyrate securin, which is subsequently degraded by proteasomes. This activates separase (see Figure 19-27).
- Exit from mitosis is triggered by mitotic CDK inactivation mainly brought about by mitotic cyclin degradation.
- Exit from mitosis requires the activity of protein phosphatases such as Cdc14 to remove mitotic phosphorylations from many different proteins, permitting mitotic spindle disassembly, the decondensation of chromosomes, and the reassembly of the nuclear envelope.
- Cytokinesis finalizes cell fission and must be coordinated with the site of nuclear division. This coordination is especially important in cells undergoing an asymmetric division.

19.7 Surveillance Mechanisms in Cell Cycle Regulation

Surveillance mechanisms known as **checkpoint pathways** operate to ensure that the next cell cycle event is not initiated until the previous one has been completed. Checkpoint pathways consist of **sensors** that monitor a particular cellular event, a **signaling cascade** that initiates the response, and an **effector** that halts cell cycle progression and activates repair pathways when necessary. Cell cycle events monitored by checkpoint pathways include growth, DNA replication, DNA damage, kinetochore attachment to the mitotic spindle, and position of the spindle within the cell. They are responsible for the extraordinarily high fidelity of cell division, ensuring that each daughter cell receives the correct number of accurately replicated chromosomes. They function by controlling the protein kinase activities of the cyclin-CDKs through a variety of mechanisms: regulation of the synthesis and degradation of cyclins, phosphorylation of CDKs at inhibitory sites, regulation of the synthesis and stability of

CDK inhibitors (CKIs) that inactivate cyclin-CDK complexes, and regulation of the APC/C ubiquitin-protein ligase.

Checkpoint Pathways Establish Dependencies and Prevent Errors in the Cell Cycle

The experiments that led to the idea of surveillance mechanisms or checkpoint pathways establishing dependencies in the cell cycle were simple and beautiful in their interpretation. Recall that Lee Hartwell and colleagues isolated temperature-sensitive *cdc* mutants in *S. cerevisiae*. Their characterization and the study of the genes affected in these mutants profoundly shaped our understanding of the eukaryotic cell cycle. It was the characterization of one of these *cdc* mutants, *cdc13*, that led Hartwell and colleagues to formulate the checkpoint pathway concept.

For the purpose of our discussion here, the only thing that is important to know about *CDC13* function is that the gene is required for telomere replication and, in its absence, large stretches of incompletely replicated telomeric DNA persist in cells. Cells carrying a temperature-sensitive allele of the *cdc13* gene as the sole source of *CDC13* arrest with a G₂ DNA content when shifted to the restrictive temperature (Figure 19-31a). This arrest is indicative of a defect in late S phase or entry into mitosis. When the cells are returned to

the permissive temperature, the temperature-sensitive protein is functional again, and cells continue to proliferate. Thus, although the *cdc13* mutant cells failed to divide at the restrictive temperature, they retained their viability and so were able to resume proliferation once they were returned to the permissive temperature where the temperature-sensitive *cdc13* protein was functional again.

To characterize the *cdc13* mutant in more detail, Hartwell and colleagues examined the effects of introducing a second mutation in another gene, a deletion in the *RAD9* gene. The *RAD9* gene is not essential for viability, but when it is deleted, cells are extremely sensitive to DNA damaging agents such as x-rays. This mutation on its own does not affect growth of cells at any temperature but had a dramatic effect on *cdc13* mutants. When the researchers examined the *cdc13 rad9* double mutant at the restrictive temperature, they observed that the mutant no longer arrested in G₂ but instead the cells continued to divide for a few divisions (Figure 19-31b). When they returned these cells to the permissive temperature, the double mutant failed to resume proliferation. This indicates that while the cells continued to divide a few times at the restrictive temperature, they lost viability.

Hartwell and colleagues proposed the following explanation for this observation: *cdc13* mutants arrest at the restrictive temperature because they harbor incompletely replicated DNA. This damaged DNA signals the cell to arrest cell cycle progression and induce repair of the damage because mitosis of cells with damaged DNA would almost certainly lead to cell death. The *RAD9* gene is part of the machinery that conveys this cell cycle arrest. In cells lacking *RAD9*, the “halt cell cycle progression” signal does not work and cells undergo mitosis despite incompletely replicated DNA. This kills the cells. Hartwell and his colleagues called this surveillance mechanism a **checkpoint pathway**.

Today we know that cells harbor multiple checkpoint pathways to ensure that a cell cycle phase does not commence before the previous one has been completed. In addition to establishing dependencies, the checkpoint pathways ensure that each aspect of chromosome replication and division occurs with accuracy. For example, a single kinetochore that fails to attach to the mitotic spindle can halt cell cycle progression in metaphase by activating the spindle assembly checkpoint.

Each checkpoint is built in the same manner. A sensor detects a defect in a particular cellular process and in response to this defect activates a signal transduction pathway. Effectors activated by the signaling pathway initiate repair of the defect and halt cell cycle progression until the defect is corrected. In what follows we will discuss the major checkpoint pathways that govern cell cycle progression.

The Growth Checkpoint Pathway Ensures That Cells Only Enter the Cell Cycle After Sufficient Macromolecule Biosynthesis

Cell proliferation requires that cells multiply through the process of cell division and that the individual cells grow through macromolecule biosynthesis. Cell growth and division are

EXPERIMENTAL FIGURE 19-31 An experiment that led to the checkpoint pathway concept. (a) When shifted to the restrictive temperature, *cdc13* mutants arrest cell cycle progression because of incomplete DNA replication. When the cells are returned to the permissive temperature, they resume proliferation because they maintained viability during the cell cycle arrest. (b) *cdc13 rad9Δ* double mutants do not arrest when shifted to the restrictive temperature because these cells cannot sense that their DNA is incompletely replicated. Cells undergo mitosis, and this leads to cell death because genetic information is lost. Therefore, cells quickly lose viability at the restrictive temperature and can no longer resume proliferation when they are returned to the permissive temperature.

separate processes, but for cells to maintain a constant size as they multiply, cell growth and division must be tightly coordinated. For example, when nutrients are limited, cells reduce their growth rate, and cell division must be down-regulated accordingly. This type of coordination between cell growth and division is especially important in unicellular organisms that experience changes in nutrient availability as part of their natural life cycle. It is therefore not surprising that surveillance mechanisms exist that adjust cell division rate according to growth rate.

In budding yeast, cell growth and division are coordinated in G_1 . In this stage of the cell cycle, the growth and division cycles are linked by making the activity of G_1 CDKs dependent on cell growth. Which aspect of growth is linked to the cell cycle? Classical experiments using protein synthesis inhibitors indicate that growth rate and hence cell cycle control by growth is determined by protein synthesis. How protein synthesis controls G_1 CDK activity is an area of active investigation. The G_1 cyclin Cln3 is subject to translational control, making levels of this cyclin especially sensitive to protein synthesis rate. However, it is clear that this is not the only mechanism. Although the molecular pathways that coordinate cell division with cell growth are not yet understood, it appears that this control is highly plastic. The length of G_1 and the *critical cell size*, that is, the size at which cells enter the cell cycle, change with nutrient availability.

S. pombe grows as a rod-shaped cell that increases in length as it grows and then divides in the middle during mitosis to produce two daughter cells of equal size (see Figure 19-4). Unlike budding yeast and most metazoan cells that grow primarily during G_1 , this yeast does most of its growing during the G_2 phase of the cell cycle and it is entry into mitosis that is carefully regulated in response to cell size. Recall entry into mitosis is regulated by the protein kinase Wee1, which inhibits CDK1 by phosphorylating tyrosine 15. When nutrients are limited, Wee1 phosphorylates CDK1; hence cells remain in G_2 until they reach the critical size for mitotic entry. This size control is brought about by regulated protein localization. The protein kinase Pom1 forms a gradient from each pole toward the middle of the cell. The CDK inhibitor Wee1 and its inhibitor Cdr2 localize in patches to the cell cortex in the middle of the cell (Figure 19-32). Pom1 prevents Cdr2 from inhibiting Wee1. When cells are small, Pom1 inhibits Cdr2. Wee1 is active and prevents entry into mitosis. As cells grow, the local concentration of Pom1 in the middle of the cell declines and Cdr2 becomes active and inhibits Wee1. Cells can now enter mitosis. Hence in this organism, cell length is measured by a protein gradient.

Nutrients are usually not limiting in multicellular organisms. Instead, cell growth is controlled by growth factor signaling pathways such as the Ras, AMPK, and TOR pathways (see Chapters 8 and 16). These pathways also appear to be important for coordinating cell growth and division. Mutations in key components of growth factor signaling pathways, such as Myc, cause dramatic changes in cell size in *Drosophila*. Myc regulates the transcription of many genes important for macromolecule biosynthesis and also, more

FIGURE 19-32 A protein gradient measures cell length in *S. pombe*. The protein kinase Pom1 forms a gradient from each pole toward the middle of the cell. Wee1 and its inhibitor Cdr2 are localized to patches of cell cortex in the middle of the cell. Pom1 inhibits Cdr2, and hence the pathway that inhibits Wee1. (a) In small cells, the concentration of Pom1 in the middle of the cell is higher. Cdr2 is inhibited, allowing Wee1 to remain active and prohibit entry into mitosis. (b) As cells grow in length, the concentration of Pom1 in the middle of the cell declines. Pom1 inhibition of Cdr2 decreases, and the Cdr2 signaling pathway is now able to inhibit Wee1, promoting entry into mitosis. [Adapted from Moseley et al., 2009; *Nature* 459:857–860.]

indirectly, G_1 CDKs. Thus this transcription factor appears to integrate cell growth and division. However, the details of this coordination remain to be elucidated.

The DNA Damage Response Halts Cell Cycle Progression When DNA Is Compromised

The complete and accurate duplication of the genetic material is essential for cell division. If cells enter mitosis when DNA is not completely replicated or otherwise damaged, genetic changes occur. In many instances, those changes will lead to cell death, but as we will see in Chapter 24, they can also lead to genetic alterations that result in loss of growth and division control and eventually cancer. This is underscored by the finding that many proteins involved in sensing DNA damage and its repair are frequently found mutated in human cancers.

The enzymes that replicate DNA are highly accurate, but this exactness is not enough to ensure complete accuracy during DNA synthesis. Furthermore, environmental insults such as x-rays and UV light can cause DNA damage, and this damage must be repaired before a cell's entry into mitosis. Cells have a **DNA damage response system** in place that senses many different types of DNA damage and responds by activating repair pathways and halting cell cycle progression until the damage has been repaired. Cell cycle arrest can occur either in G_1 , S phase, or G_2 , depending on whether DNA damage occurred before cell cycle entry or during DNA replication. In multicellular organisms, the strategy to deal with particularly severe DNA damage is different. Rather than attempting to repair the damage, cells undergo **programmed cell death** or **apoptosis**, a mechanism that we will discuss in detail in Chapter 21.

DNA damage exists in many different forms and ranges in severity. A break of the DNA helix, known as a **double-strand**

break, is perhaps the most severe form of damage since such a lesion would almost certainly lead to DNA loss if mitosis ensued in its presence. More subtle defects include single-strand breaks, structural changes in nucleotides, or DNA mismatches. For our discussion here, it is important to note that cells have sensors for all these different types of damage. These sensors scan the genome and, when they detect a lesion, assemble signaling and repair factors onto the site of the lesion.

Central to the detection of the different lesions is a pair of homologous protein kinases called ATM and ATR. These protein kinases get recruited to sites of DNA damage. They then initiate the sequential recruitment of adapter proteins and another set of protein kinases called Chk1 and Chk2. These kinases then activate repair mechanisms and cause cell cycle arrest or apoptosis in animals (Figure 19-33). ATR and ATM recognize different types of DNA damage. ATM is very specialized in that it only responds to double-strand breaks. ATR is able to recognize more diverse types of DNA damage, such as stalled replication forks, damaged nucleotides, and double-strand breaks. ATR recognizes these diverse types of damage because all of them contain some amount of *single-stranded DNA*, either as part of the damage itself or because repair enzymes create single-stranded DNA as part of the repair process. Stalled replication forks, for example, are recognized by ATR. The association of ATR with stalled forks is

FIGURE 19-33 The DNA damage response system. The protein kinases ATM and ATR are activated by damaged DNA. ATR responds to a variety of DNA damage—most likely to the single-stranded DNA that exists either as a result of the damage itself or as a result of repair. ATM is specifically activated by double-strand breaks. Because double-strand breaks are converted into single-stranded DNA as a result of repair, they also, albeit indirectly and hence depicted as a dashed line, activate ATR. ATM and ATR, once activated by DNA damage, activate another pair of related protein kinases, Chk1 and Chk2. These kinases then induce the DNA repair machinery and cause cell cycle arrest by inhibiting Cdc25. In metazoan cells, when the DNA damage is severe, Chk1 and Chk2 also activate the transcription factor p53. p53 induces cell cycle arrest by inducing transcription of the CKI p21 and apoptosis.

thought to activate its protein kinase activity, leading to the recruitment of adapter proteins whose function is to recruit and help activate the Chk1 kinase. Active Chk1 then induces repair pathways and inhibits cell cycle progression.

Chk1 and Chk2 halt the cell cycle. The protein kinases phosphorylate Cdc25, thereby inactivating it (see Figure 19-33). When the DNA damage occurs during G_1 , Cdc25A inhibition results in inhibition of G_1/S phase CDKs and S phase CDKs (Figure 19-34). As a result, these kinases cannot initiate DNA replication. When the DNA damage occurs during S phase or in G_2 , Cdc25C inhibition by Chk1/2 results in the inhibition of mitotic CDKs and hence arrest in G_2 . Active DNA replication also inhibits entry into mitosis. ATR continues to inhibit Cdc25C via Chk1 until all replication forks complete DNA replication and disassemble. This mechanism makes the initiation of mitosis *dependent* on the completion of chromosome replication. Finally, cells also sense DNA replication stress that results in stalled or slowing of replication forks. It triggers activation of the ATR-Chk1 checkpoint pathway and results in down-regulation of S phase CDK activity and prevents firing of late-replicating origins.

Chk1-mediated inhibition of the Cdc25 family of phosphatases is not the only mechanism whereby DNA damage or incomplete replication inhibits cell cycle progression. As we will see below, DNA damage leads to the activation of the transcription factor p53, which transcribes the CDK inhibitor p21. p21 binds to and inhibits all metazoan cyclin-CDK complexes. As a result, cells are arrested in G_1 and G_2 (see Figure 19-34).

ATM recognizes double-strand breaks (see Figure 19-33). The protein kinase gets directly recruited to the DNA ends by a complex known as the MRN complex, which binds to broken ends and holds them together. Activated ATM then phosphorylates and activates Chk2 and recruits repair proteins. These repair proteins initiate **homologous recombination**, as discussed in Chapter 4. This process involves the creation of single-stranded overhangs, which in turn recruit and activate ATR and its effectors, further enhancing the DNA damage response. ATM can also recruit an alternative repair pathway where two double-strand breaks are directly fused with each other in a repair process known as **nonhomologous end joining**. Like ATR, ATM activation also halts cell cycle progression by a Chk2-mediated inhibition of Cdc25, thus preventing activation of CDKs. This inhibition can occur in G_1 or G_2 .

A key effector of the DNA damage response in metazoan cells is the transcription factor p53 (see Figure 19-33). It is known as a tumor suppressor because its normal function is to limit cell proliferation in the face of DNA damage. The protein is extremely unstable and generally does not accumulate to high enough levels to stimulate transcription under normal conditions. The instability of p53 results from its ubiquitinylation by a ubiquitin-protein ligase called *Mdm2* and subsequent proteasomal degradation. The rapid degradation of p53 is inhibited by ATM and ATR, which phosphorylate p53 at a site that interferes with Mdm2 binding. This and other modifications of p53 in response to DNA damage greatly increase its ability to activate transcription of

FIGURE 19-34 Overview of DNA damage checkpoint controls in the cell cycle. During G_1 , the $p53$ - $p21^{CIP}$ pathway inhibits G_1 CDKs. During ongoing DNA replication and in response to replication stress (slow DNA replication fork movement or DNA replication fork collapse), the ATR-Chk1 protein kinase cascade phosphorylates and inactivates Cdc25C, thereby preventing the activation of mitotic CDKs and inhibiting entry into mitosis. In response to DNA damage, the ATM or

ATR protein kinases (ATM/R) inhibit Cdc25 via the Chk1/2 protein kinases. They also activate $p53$, which induces production of the CKI $p21$. During G_1 , the DNA damage checkpoint pathway inhibits Cdc25A inhibiting G_1/S phase CDKs and S phase CDKs, thereby blocking entry into or passage through S phase. During G_2 , ATM/R-Chk1/2 inhibit Cdc25C. The $p53$ - $p21^{CIP}$ pathway is also activated. Red symbols indicate pathways that inhibit progression through the cell cycle.

specific genes that help the cell cope with DNA damage. One of these genes encodes the CKI $p21$ (see Figure 19-34).

Under some circumstances, such as when DNA damage is extensive, $p53$ also activates expression of genes that lead to apoptosis, the process of programmed cell death that normally occurs in specific cells during the development of multicellular animals. In metazoans, the $p53$ response evolved to induce apoptosis in the face of extensive DNA damage, presumably to prevent the accumulation of multiple mutations that might convert a normal cell into a cancer cell. The dual role of $p53$ in both cell cycle arrest and the induction of apoptosis may account for the observation that nearly all cancer cells have mutations in both alleles of the $p53$ gene or in the pathways that stabilize $p53$ in response to DNA damage (see Chapter 24). The consequences of mutations in $p53$, ATM , and $Chk2$ provide dramatic examples of the significance of cell cycle checkpoint pathways to the health of a multicellular organism.

The Spindle Assembly Checkpoint Pathway Prevents Chromosome Segregation Until Chromosomes Are Accurately Attached to the Mitotic Spindle

The spindle assembly checkpoint pathway prevents entry into anaphase until every kinetochore of every chromatid is properly attached to spindle microtubules. If even a single kinetochore is unattached or not under tension, anaphase is inhibited. Clues about how this checkpoint operates initially came from the isolation of yeast mutants with a defective response to benomyl, a microtubule-depolymerizing drug. Low concentrations of benomyl increase the time required for yeast cells to assemble the mitotic spindle and attach kinetochores to microtubules. Wild-type cells exposed to benomyl do not begin anaphase until these processes are completed and then proceed on through mitosis, producing normal daughter cells. In contrast, mutants defective in the spindle

assembly checkpoint pathway proceed through anaphase before assembly of the spindle and attachment of kinetochores is complete; consequently, they mis-segregate their chromosomes, producing abnormal daughter cells that die.

We now know that cells harbor a surveillance mechanism that prevents anaphase entry in the presence of unattached kinetochores. Components of the spindle assembly checkpoint recognize and bind to unoccupied microtubule binding sites at kinetochores and create an anaphase inhibitory signal (Figure 19-35a). A protein known as Mad2 (*mitotic arrest defective 2*) is central to the creation of this inhibitory signal. Mad2 regulates Cdc20, the specificity factor required to target the APC/C to securin. Recall that APC/C^{Cdc20}-mediated ubiquitylation of securin and its subsequent degradation is required for activation of separase and entry into anaphase (see

Figure 19-27). Mad2 is recruited to kinetochores that are not attached to microtubules. Mad1 appears critical for this process. Kinetochores bound Mad2 rapidly exchanges with a soluble form of Mad2 that inhibits all the Cdc20 in the cell (Figure 19-35a). When microtubules attach to kinetochores, the kinetochores release the bound Mad2 and cease the process by which the inhibitory, soluble form of Mad2 is produced (Figure 19-35b). However, when even a single kinetochore is unattached to microtubules from the opposite spindle pole of its sister, sufficient soluble inhibitory Mad2 is produced at the unattached kinetochore to inhibit all the Cdc20 in the cell. This elegant model for the spindle assembly checkpoint pathway can account for the ability of a single unattached kinetochore to inhibit all the cellular Cdc20 until the kinetochore becomes properly associated with spindle microtubules.

FIGURE 19-35 The spindle assembly checkpoint pathway. The spindle assembly checkpoint pathway is active until every single kinetochore has attached properly to spindle microtubules. (a) The Mad2 protein exists in two conformations, one “open” (red squares) and the other “closed” (orange circles). According to the current model, Mad1 and the closed Mad2 form a tetramer that binds to unattached kinetochores via the Mad1 subunit (step 1). Open Mad2 can bind transiently to closed Mad2 bound to Mad1 at the kinetochore (step 2). This interaction with closed Mad2 stimulates open Mad2 to bind a Cdc20. Open Mad2 can bind Cdc20 only while it is interacting with a closed Mad2. This converts the open Mad2 protein to the closed conformation, causing it to dissociate from the closed Mad2 at the kinetochore (step 3). The stable interaction of closed Mad2 with Cdc20 prevents Cdc20 from binding to the APC/C. Further, the closed Mad2 bound to Cdc20 can interact transiently with another Mad2 in the open conformation (step 4), causing it to bind another Cdc20 molecule. This converts the open Mad2 to the closed conformation bound to Cdc20. This newly formed closed Mad2-Cdc20 complex dissociates from the first Mad2-Cdc20 pair, generating two Mad2-Cdc20 complexes (step 5). Thus free Mad2 in the open conformation is quickly converted to closed Mad2 bound to Cdc20

as this cycle repeats (step 5). The source of closed Mad2 that initiates this chain reaction is the closed Mad2 bound to Mad1 associated with a kinetochore, explaining how a single unattached kinetochore can cause inactivation of all the Cdc20 in the cell through the formation of closed Mad2-Cdc20 complexes. How are unattached kinetochores that recruit Mad1-Mad2 complexes generated? Either microtubules fail to attach or Aurora B severs kinetochore-microtubule attachments that are not under tension (see Figure 19-25). (b) Silencing of the spindle assembly checkpoint pathway: Attachment of microtubules (green) to kinetochores causes the displacement of the Mad1-Mad2 tetramer. Mad2 in the displaced tetramer cannot interact with open Mad2 but rather binds to p31^{comet}. p31^{comet} is always active and disassembles Mad2-Cdc20 complexes, releasing active Cdc20 (step 7). However, a small number of Mad1-Mad2 tetramers bound to kinetochores can generate enough Mad2-Cdc20 complexes by the mechanism shown in (a) to overcome the activity of p31. Once all kinetochores have attached to microtubules, causing the release of all Mad1-Mad2 tetramers, p31 activity predominates, releasing active Cdc20, which binds to the APC/C, resulting in ubiquitylation and proteasomal degradation of securin and the onset of anaphase. [Modified from A. De Antoni et al., 2005, *Curr. Biol.* 15:214.]

Entry into anaphase is also inhibited when the attachments of microtubules to kinetochores are faulty. As we saw in Section 19.5, kinetochores of sister chromatids often attach to microtubules emanating from the same pole (syntelic attachment) or a single kinetochore attaches to microtubules that originate from two different poles (merotelic attachment). These faulty attachments result in insufficient or no tension at sister kinetochores, and such microtubule-kinetochore interactions are quickly destabilized by Aurora B phosphorylation of the microtubule-binding proteins of the kinetochore. This leads to the generation of unattached kinetochores, which are recognized by the spindle assembly checkpoint. In this manner Aurora B and the spindle assembly checkpoint collaborate during every cell cycle to accurately attach every single pair of sister chromatids on the mitotic spindle in the correct, bi-oriented manner.

The spindle assembly checkpoint pathway is essential for viability in mice, highlighting the importance of this quality-control pathway during every cell division. If anaphase is initiated before both kinetochores of a replicated chromosome become attached to microtubules from opposite spindle poles, daughter cells are produced that have missing or extra chromosomes, an outcome called *nondisjunction*. When nondisjunction occurs in mitotic cells, it can lead to the misregulation of genes and contribute to the development of cancer. When nondisjunction occurs during the meiotic division that generates a human egg or sperm, trisomy of any chromosome can occur. Down syndrome is caused by trisomy of chromosome 21, resulting in developmental abnormalities and mental retardation. Every other trisomy results in embryonic lethality or death shortly after birth.

The Spindle Position Checkpoint Pathway Ensures That the Nucleus Is Accurately Partitioned Between Two Daughter Cells

The coordination of the site of nuclear division with that of cytokinesis is essential for the production of two identical daughter cells. If cytokinesis occurred in such a way that each daughter cell failed to receive a complete genetic complement, chromosome loss or gain would ensue. In many systems, surveillance mechanisms have been described that ensure cytokinesis does not occur when the mitotic spindle is not correctly positioned in the cell. This surveillance mechanism, known as the **spindle position checkpoint pathway**, is best understood in budding yeast. In budding yeast, the site of bud formation and therefore the site of cytokinesis is determined during G_1 . Thus the axis of division is defined prior to mitosis and the mitotic spindle must be aligned along this mother-bud axis during every cell division (Figure 19-36, step 1). When this process fails, the spindle position checkpoint prevents mitotic CDK inactivation, giving the cell an opportunity to reposition the spindle prior to spindle disassembly and cytokinesis (Figure 19-36, step 2). If the spindle position checkpoint fails, cells that misposition their spindles give rise to mitotic products with too many or too few nuclei (Figure 19-36, step 3).

FIGURE 19-36 The spindle position checkpoint in budding yeast. Cdc14 phosphatase activity is required for exit from mitosis. *Top:* In *S. cerevisiae*, during interphase and early mitosis, Cdc14 (red dots) is sequestered and inactivated in the nucleolus. Inactive Tem1-GDP (purple) associates with the spindle pole body (SPB) nearest to the bud as soon as the mitotic spindle forms. If chromosome segregation occurs properly (step 1), extension of the spindle microtubules inserts the daughter SPB into the bud, causing Tem1 to be activated by an unknown mechanism. Tem1-GTP activates a protein kinase cascade, which then promotes the release of active Cdc14 from the nucleolus and exit from mitosis. If the spindle apparatus fails to place the daughter SPB in the bud (step 2), Kin4 (cyan), an inhibitor of Tem1, is recruited from the mother cell cortex to the mother-cell-located SPB and maintains Tem1 in the GDP bound form and mitotic exit does not occur. Lte1 (orange) is an inhibitor of Kin4 and localized to the bud. Lte1 prevents Kin4 that leaks into the bud from inhibiting Tem1. If the checkpoint fails (step 3), cells with mispositioned spindles inappropriately exit from mitosis and produce anucleate and multi-nucleate cells.

Recall that in budding yeast, a pool of mitotic cyclins are spared from degradation by APC/C^{Cdc20} to facilitate the sometimes difficult process of aligning the mitotic spindle in such a way that half the nucleus squeezes through the tiny bud neck during anaphase spindle elongation. Recall further that inactivation of this protected pool of mitotic cyclin-CDK complexes is triggered by the protein phosphatase Cdc14, which in turn is activated by a signal transduction pathway known as the *mitotic exit network* (see Figure 19-28). The mitotic exit network is controlled by a small (monomeric) GTPase called *Tem1*. This member of the GTPase superfamily of switch proteins controls the activity of a protein kinase cascade similarly to the way Ras controls MAP kinase pathways (see Chapter 16). *Tem1* associates with spindle pole bodies (SPBs) as soon as they form. An inhibitor of the GTPase called *Kin4* localizes to the mother cell but is absent from the bud (see Figure 19-36). An inhibitor of *Kin4* called *Lte1* localizes to the bud but is absent from the mother cell and inhibits any residual *Kin4* that leaks into the bud. When spindle microtubule elongation at the end of anaphase has correctly positioned segregating daughter chromosomes into the bud, *Tem1* inhibition by *Kin4* is relieved. As a consequence, *Tem1* is converted into its active GTP-bound state, activating the protein kinase signaling cascade. The terminal kinase in the cascade then phosphorylates the nucleolar anchor that binds and inhibits Cdc14, releasing the Cdc14 phosphatase into the cytoplasm and nucleoplasm in both the bud and mother cell (see Figure 19-36, step 1). Once active Cdc14 is available, mitotic CDKs are inactivated and cells exit from mitosis. When the spindle fails to position correctly, the *Tem1*-bearing spindle pole body fails to enter the bud and the mitotic exit network cannot be activated. Cells arrest in anaphase. Thus spatial restriction of inhibitors and activators of a signal transduction pathway allows the cell to sense a spatial cue, spindle position, and translate it into regulation of a signal transduction pathway.

KEY CONCEPTS of Section 19.7

Surveillance Mechanisms in Cell Cycle Regulation

- Surveillance mechanisms known as checkpoint pathways establish dependencies among cell cycle events and ensure that cell cycle progression does not occur prior to the completion of a preceding event.
- Checkpoint pathways consist of sensors that monitor a particular cellular event or defect therein, a signaling pathway, and an effector that halts cell cycle progression and activates repair pathways when necessary.
- Growth and cell division are integrated during G₁ in most systems. Reduced macromolecule biosynthesis delays cell cycle entry.
- Cells are able to detect and respond to a wide variety of DNA damage, and the response differs depending on the cell cycle stage that cells are in.

- In response to DNA damage two related protein kinases ATM and ATR are recruited to the site of damage, where they activate signaling pathways that lead to cell cycle arrest, repair, and, under some circumstances, apoptosis.
- The spindle assembly checkpoint pathway, which prevents premature initiation of anaphase, utilizes Mad2 and other proteins to regulate the APC/C specificity factor Cdc20, which targets securin and mitotic cyclins for ubiquitinylation.
- The spindle position checkpoint pathway prevents mitotic CDK inactivation when the spindle is mispositioned. In this pathway localized activators and inhibitors and a sensor that shuttles between them allows the cells to sense spindle position.

19.8 Meiosis: A Special Type of Cell Division

In nearly all diploid eukaryotes, meiosis generates haploid germ cells (eggs and sperm), which can then fuse with a germ cell from another individual to generate a diploid zygote that develops into a new individual. Meiosis is a fundamental aspect of the biology and evolution of all eukaryotes because it results in the reassortment of the chromosome sets received from an individual's two parents. Both chromosome reassortment and **homologous recombination** between parental DNA molecules during meiosis guarantees that each haploid germ cell generated will receive a unique combination of gene alleles that is distinct from each parent as well as from every other haploid germ cell formed.

The mechanisms of meiosis are analogous to those of mitosis. However, several key differences in meiosis allow this process to generate haploid cells with genetic diversity (see Figure 5-3). In mitosis, each S phase is followed by chromosome segregation and cell division. In contrast, during meiosis, one round of DNA replication is followed by *two consecutive chromosome segregation phases*. This leads to the formation of haploid rather than diploid daughter cells. During the two divisions, maternal and paternal chromosomes are shuffled and divided so that the daughter cells are different in genetic makeup from the parent cell. In this section, we will discuss the similarities between mitosis and meiosis as well as the meiosis-specific mechanisms that transform the canonical mitotic cell cycle machinery so that it brings about the unusual cell division that leads to the formation of haploid daughter cells.

Extracellular and Intracellular Cues Regulate Entry into Meiosis

The signals triggering entry into the meiotic divisions in metazoans are a very active area of research and much is still unknown. However, the same basic principles govern the decision to enter the meiotic program in all organisms where this has been studied. Extracellular signals induce a transcriptional program that produces meiosis-specific cell cycle

factors that bring about the unusual meiotic cell divisions. This modification of the cell cycle goes hand in hand with a developmental program that induces the features characteristic of gametes, such as the development of a flagellum in sperm or the production of a stress-resistant cell wall during spore formation in fungi. At least one of the extracellular signals inducing entry into the meiotic divisions in mammals is retinoic acid, a steroid hormone that functions in many different developmental processes. The cellular targets of this hormone and how it functions to specify the meiotic fate remain to be discovered.

The molecular mechanisms underlying the decision to enter the meiotic divisions are well understood in *S. cerevisiae*. The decision to enter the meiotic divisions is made in

G_1 . Depletion of nitrogen and carbon sources induces diploid cells to undergo meiosis instead of mitosis, yielding haploid spores (see Figure 1-17). During the meiotic divisions, budding is repressed and pre-meiotic S phase and the two meiotic divisions occur within the confines of the mother cell. Spore walls are then produced around the four meiotic products. Recall that budding and the initiation of DNA replication are induced by G_1/S phase CDKs. Their expression needs to be inhibited to prevent budding. Nutritional starvation represses expression of G_1/S phase cyclins, inhibiting budding. However, DNA replication also relies on G_1/S phase CDKs. How can pre-meiotic DNA replication occur in the absence of G_1/S phase CDKs? The sporulation-specific protein kinase Ime2 takes over the role of G_1/S phase CDKs

FIGURE 19-37 Comparison of the main features of mitosis and meiosis. [Adapted from A. J. F. Griffiths et al., 1999, *Modern Genetic Analysis*, W. H. Freeman and Company.]

in promoting DNA replication. Ime2 promotes (1) phosphorylation of the APC/C specificity factor Cdh1, inactivating it so that S phase and M phase cyclins can accumulate; (2) phosphorylation of transcription factors to induce genes required for S phase, including DNA polymerases and S phase cyclins; and (3) phosphorylation of the S phase CDK inhibitor Sic1, leading to release of active S phase CDKs and the onset of pre-meiotic DNA replication.

Several Key Features Distinguish Meiosis from Mitosis

The meiotic divisions differ in several fundamental aspects from the mitotic divisions. These are summarized in Figure 19-37. During meiosis, a single round of DNA replication is followed by two cycles of cell division, termed *meiosis I* and *meiosis II* (Figure 19-38). Meiosis II resembles mitosis in that sister chromatids are segregated. However, meiosis I is very different. During this division, homologous chromosomes—the chromosome inherited from your mother and the same chromosome inherited from your father—are segregated. This unusual chromosome segregation requires three meiosis-specific modifications to the chromosome segregation machinery. In what follows we will discuss these and explain why they are needed.

The tension-based sensing mechanism responsible for accurately attaching chromosomes to the spindle during mitosis is also responsible for segregating chromosomes during meiosis I. Thus homologous chromosomes must be linked so that the tension-based mechanism of accurate attachment to the spindle can function. **Homologous recombination** between homologous chromosomes creates these linkages (see Figure 19-38). The molecular mechanisms of homologous recombination are discussed in detail in Chapter 4. Here, we will restrict our discussion to the importance of homologous recombination for the meiotic divisions to occur successfully.

In G₂ and prophase of meiosis I, the two replicated chromatids of each chromosome are associated with each other by cohesin complexes along the full length of the chromosome arms, just as they are following DNA replication in a mitotic cell cycle (see Figure 19-38). In prophase of meiosis I, homologous chromosomes (i.e., the maternal and paternal chromosome 1, the maternal and paternal chromosome 2, etc.) pair with each other and undergo homologous recombination. Significantly, at least one recombination event occurs between a maternal and a paternal chromosome. The **crossing over** of chromatids produced by recombination can be observed microscopically in the first meiotic prophase and metaphase as structures called *chiasmata* (singular, *chiasma*). In contrast, no pairing between homologous chromosomes occurs during mitosis, and recombination between nonsister chromatids is rare. Concomitant with homologous recombination, homologous chromosomes associate with each other in a process known as *synapsis*. In most organisms this synapsis is mediated by a proteinaceous complex known as the **synaptonemal complex (SC)**. Homologous chromosomes linked through chiasmata are called bivalents

(see Figure 19-38). The chiasmata now provide the resistance to the pulling force exerted by microtubules on the metaphase I spindle (Figure 19-39).

The recombination between nonsister chromatids that occurs in prophase of meiosis I has at least two functional consequences: First, it holds homologous chromosomes together during meiosis I metaphase. Second, it contributes to genetic diversity among individuals of a species by ensuring new combinations of gene alleles in different individuals. (Note: genetic diversity primarily arises from the independent reassortment of maternal and paternal homologs during the meiotic divisions). The homologs connected through at least one chiasma, which formed during prophase of meiosis I, must now align on the meiosis I spindle so that maternal and paternal chromosomes are segregated away from each other during anaphase of meiosis I. This requires that the kinetochores of sister chromatids attach to spindle fibers emanating from the *same* spindle pole rather than from opposite spindle poles as in mitosis (see Figure 19-39). Sister chromatids are said to be **co-oriented**. However, the kinetochores of the maternal and paternal chromosomes of each bivalent attach to spindle microtubules from opposite spindle poles; they are **bi-oriented**.

Finally, to facilitate two consecutive chromosome segregation phases, cohesins have to be lost from chromosomes in a stepwise manner. Recall that during mitosis, all cohesins are lost by the onset of anaphase (Figure 19-40a). In contrast, during meiosis, cohesins are lost from chromosome arms by the end of meiosis I, but a pool of cohesins around kinetochores is protected from removal (Figure 19-40b). This pool of cohesins persists throughout meiosis I but is removed at the onset of anaphase II. As we will see next, loss of cohesins from chromosome arms is required for homologous chromosomes to segregate away from each other during meiosis I.

The mechanisms that remove cohesins during meiosis are the same as during mitosis. Securin degradation releases separase, which then cleaves the cohesins holding the chromosome arms together. This allows the recombined maternal and paternal chromosomes to separate, but each pair of chromatids remains associated at the centromere. During metaphase II, sister chromatids align on the metaphase II spindle and separase is activated yet again, cleaving the residual cohesin around centromeres, facilitating anaphase II (see Figure 19-40b).

Recombination and a Meiosis-Specific Cohesin Subunit Are Necessary for the Specialized Chromosome Segregation in Meiosis I

As discussed earlier, in metaphase of meiosis I, both sister chromatids in one (replicated) chromosome associate with microtubules emanating from the *same* spindle pole rather than from opposite poles as they do in mitosis (see Figure 19-39). Two physical links between homologous chromosomes resist the pulling force of the spindle until anaphase: (a) crossing over between chromatids, one from each pair of homologous

FOCUS ANIMATION: Meiosis

FIGURE 19-38 Meiosis. Pre-meiotic cells have two copies of each chromosome ($2n$), one derived from the paternal parent and one from the maternal parent. For simplicity, the paternal and maternal homologs of only one chromosome are diagrammed. **Step 1:** All chromosomes are replicated during S phase before the first meiotic division, giving a $4n$ chromosomal complement. Cohesin complexes (not shown) link the sister chromatids composing each replicated chromosome along their full lengths. **Step 2:** As chromosomes condense during the first meiotic prophase, replicated homologs pair and undergo homologous recombination, leading to at least one crossover event. At metaphase, shown here, both chromatids of one chromosome associate with microtubules emanating from one spindle pole, but each member of a homologous chromosome pair associates with microtubules emanating from opposite poles. **Step 3:** During anaphase of meiosis I, the homologous chromosomes, each consisting of two chromatids, are pulled to opposite spindle poles. **Step 4:** Cytokinesis yields the two daughter cells (now $2n$), which enter meiosis II without undergoing DNA replication. At metaphase of meiosis II, shown here, the sister chromatids associate with spindle microtubules from opposite spindle poles, as they do in mitosis. **Steps 5 and 6:** Segregation of sister chromatids to opposite spindle poles during the second meiotic anaphase followed by cytokinesis generates haploid gametes ($1n$) containing one copy of each chromosome. Micrographs on the left show meiotic metaphase I and metaphase II in developing gametes from *Lilium* (lily) ovules. Chromosomes are aligned at the metaphase plate. [Photos courtesy of Ed Reschke/Peter Arnold, Inc.]

FIGURE 19-39 Chiasmata and cohesins distal to them link homologous chromosomes in meiosis I metaphase. Connections between chromosomes during meiosis I are most easily visualized in organisms with acrocentric centromeres, such as the grasshopper. The kinetochores at the centromeres of sister chromatids attach to spindle microtubules emanating from the same spindle pole, with the kinetochores of the maternal (red) and paternal (blue) chromosomes attaching to spindle microtubules from opposite spindle poles. The maternal and paternal chromosomes are attached at the chiasmata which are formed by recombination between them and the cohesion between sister chromatid arms that persists throughout meiosis I metaphase. Note that elimination of cohesion between sister chromatid arms is all that is required for the homologous chromosomes to separate at anaphase. [Adapted from L. V. Pallulis and R. B. Nicklas, 2000, *J. Cell Biol.* **150**:1223.]

chromosomes, and (b) cohesins distal to the crossover point (see Figure 19-40b, *top*). Evidence for the function of recombination during meiosis comes from the observation that when recombination is blocked by mutations in proteins essential for the process, chromosomes segregate randomly during meiosis I; that is, homologous chromosomes do not necessarily segregate to opposite spindle poles.

At the onset of meiotic anaphase I, cohesins between chromosome arms are cleaved by separase. This cleavage is required for homologous chromosomes to segregate. If cohesins were not lost from chromosome arms, the recombined sister chromatid would rip during anaphase I. The maintenance of centromeric cohesion during meiosis I is necessary for the proper segregation of sister chromatids during meiosis II.

Studies in many organisms have shown that a specialized cohesin subunit, *Rec8*, is necessary for the stepwise loss of cohesins from chromosomes during meiosis. Expressed only during meiosis, *Rec8* is homologous to *Scc1*, the cohesin subunit that closes the cohesin ring in the cohesin complex of mitotic cells. Immunolocalization experiments revealed that during early anaphase of meiosis I, *Rec8* is lost from chromosome arms but is retained at centromeres. However, during early anaphase of meiosis II, centromeric *Rec8* is

FIGURE 19-40 Cohesin function during mitosis and meiosis. (a) During mitosis, sister chromatids generated by DNA replication in S phase are initially linked by cohesin complexes along the length of the chromatids. During chromosome condensation, cohesin complexes (yellow) become restricted to the region of the centromere at metaphase. Mei-S332/Sgo1 (purple) recruits PP2A to centromeres, where they antagonize Polo kinase and Aurora B, preventing the dissociation of cohesins from centromeric regions. Dissociation of Mei-S332/Sgo1 from centromeres and activation of separase leads to removal of cohesins at the centromere. Sister chromatids now separate, marking the onset of anaphase. (b) In prophase of meiosis I, maternal and paternal chromatids establish linkages between each other by homologous recombination. By metaphase I, the chromatids of each replicated chromosome are cross-linked by cohesin complexes along their full length. *Rec8*, a meiosis-specific homolog of *Scc1*, is cleaved along chromosome arms but not around the centromere, allowing homologous chromosome pairs to segregate to daughter cells. Centromeric *Rec8* is protected from cleavage by PP2A, recruited to centromeric regions by the PP2A regulator Mei-S332/Sgo1 (shown in purple). By metaphase II, the Mei-S332/Sgo1-PP2A complex dissociates from chromosomes. Cohesins can now be cleaved during meiosis II, allowing sister chromatids to segregate. [Modified from F. Uhlmann, 2001, *Curr. Opin. Cell Biol.* **13**:754.]

cleaved by separase, so the sister chromatids can segregate, as they do in mitosis (see Figure 19-40b, *bottom*). Consequently, understanding the regulation of *Rec8*-cohesin complex cleavage is central to understanding chromosome segregation in meiosis I.

The mechanism that protects *Rec8* from cleavage at centromeres during meiosis I is similar to the mechanism that protects *Scc1* at centromeres during mitosis. Recall that during mitotic prophase, protein kinases, chief among them Polo

kinase, phosphorylate cohesins in the chromatid arms, causing them to dissociate and eliminating cohesion on chromatid arms by metaphase. However, cohesion at the centromeres is maintained because a specific isoform of protein phosphatase 2A (PP2A) is localized to centromeric chromatin by members of a family of proteins known as the Mei-S332/Shugoshin. PP2A keeps cohesin in a hypophosphorylated state that does not dissociate from chromatin (see Figure 19-40a). During metaphase II, Mei-S332/Sgo1 dissociates from chromosomes. In addition, when the last kinetochore is properly associated with spindle microtubules, Cdc20 is derepressed and associates with the APC/C, causing ubiquitinylation of securin. This releases separase activity, which cleaves Scc1 whether it is phosphorylated or not, eliminating cohesion at the centromere and allowing chromatid separation in anaphase (see Figure 19-40a).

Cohesin removal differs for meiosis I because when Rec8 replaces Scc1 in the cohesin complex, the complex does not dissociate in prophase when it is phosphorylated. The meiotic cohesin complex can only be removed from chromatin via the action of separase. Rec8 also differs from Scc1 in that it must be phosphorylated by several protein kinases to be cleaved by separase. During meiosis I, the centromere-specific isoform of PP2A targeted to centromeric chromatin by Mei-S332/Shugoshin prevents this phosphorylation. The PP2A targeting factor and PP2A then dissociate from chromosomes by metaphase II, allowing separase cleavage of Rec8.

Co-orienting Sister Kinetochores Is Critical for Meiosis I Chromosome Segregation

As discussed earlier, in mitosis and meiosis II, sister kinetochores attach to spindle microtubules emanating from *opposite* spindle poles; the kinetochores are said to be *bi-oriented*. This is essential for segregation of sister chromatids to different daughter cells. In contrast, at meiosis I metaphase, sister kinetochores attach to spindle microtubules emanating from the *same* spindle pole; the sister kinetochores are said to be *co-oriented* (see Figure 19-39). Obviously, attachment of sister kinetochores to the proper microtubules in meiosis I and II is critical for correct meiotic segregation of chromosomes.

Proteins required for meiosis I sister kinetochore co-orientation were first identified in *S. cerevisiae*. We now know that a protein complex known as the **monopolin complex** associates with kinetochores during meiosis I and links sister kinetochores to favor attachment to microtubules emanating from the same spindle pole. In organisms where kinetochores attach to multiple microtubules, Rec8-containing cohesins are essential for sister kinetochore co-orientation. These meiosis-specific cohesins impose a rigid kinetochore structure, restricting the movement of sister kinetochores and thereby favoring attachment to microtubules from the same spindle pole.

Like during mitosis and meiosis II, correct attachment of meiosis I chromosomes is mediated by a tension-based mechanism.

During meiotic metaphase I, kinetochore-associated microtubules are also under tension (even though the co-oriented kinetochores of sister chromatids attach to microtubules coming from the same spindle pole) because chiasmata generated by recombination between homologous chromosomes and the cohesins distal to the chiasmata prevent them from being pulled to the poles (see Figure 19-39). Since kinetochore-microtubule attachments are unstable in the absence of tension (due to Aurora B-mediated phosphorylation), kinetochores that attach to the wrong spindle fibers release the incorrect microtubules, enabling them to bind microtubules again until attachments are made that generate tension. As in mitosis, once tension is generated, microtubule attachment to the kinetochores is stabilized.

DNA Replication Is Inhibited Between the Two Meiotic Divisions

The mechanism by which DNA replication is suppressed between meiosis I and II is currently an active area of investigation, but it is thought that a change in the regulation of CDK activity is at least in part responsible for this suppression. The same S phase CDKs that promote DNA replication prior to mitosis are needed for pre-meiotic DNA replication. The same mitotic CDKs that promote mitosis also promote the meiotic divisions, except we now call mitotic CDKs meiotic CDKs since they promote the meiotic divisions and not mitosis.

So how is DNA replication prevented between the two meiotic divisions? Following anaphase of meiosis I, meiotic CDK activity does not fall as low as it does following mitotic anaphase. This partial drop in CDK activity is thought to be sufficient to promote the disassembly of the meiosis I spindle but insufficient to promote MCM helicase loading (recall a state of very low or no CDK activity is needed to load MCM helicases). During prophase of meiosis II, meiotic CDK activity rises again and the meiosis II spindle forms. After all sister kinetochores have attached to microtubules from opposite spindle poles, separase is activated and cells proceed through meiosis II anaphase, telophase, and cytokinesis to generate haploid germ cells.

KEY CONCEPTS of Section 19.8

Meiosis: A Special Type of Cell Division

- Meiosis is a specialized division in which meiosis-specific gene products modulate the mitotic cell division program (see Figure 19-38).
- The meiotic division comprises one cycle of chromosome replication followed by two cycles of cell division to produce haploid germ cells from a diploid pre-meiotic cell. During meiosis I, homologous chromosomes are segregated; during meiosis II sister chromatids separate.
- Specialized environmental conditions induce a developmental program that leads to the meiotic divisions.

- During prophase of meiosis I, homologous chromosomes undergo recombination. At least one recombination event occurs between chromatids of homologous chromosomes, linking the homologous chromosomes.
- Cohesins distal to the chiasma are responsible for holding the homologous chromosomes together during prophase and metaphase of meiosis I.
- At the onset of anaphase of meiosis I, cohesins on chromosome arms are phosphorylated and as a result cleaved by separase, but cohesins in the region of the centromere are protected from phosphorylation and cleavage. This protection is brought about by a meiosis-specific cohesin subunit and a protein phosphatase that associates with centromeres. As a result, the chromatids of homologous chromosomes remain associated during segregation in meiosis I.
- Cleavage of centromeric cohesins during anaphase of meiosis II allows individual chromatids to segregate into germ cells.
- A complex of meiosis-specific kinetochore proteins, known as the monopolin complex, promote the co-orientation of sister chromatids during meiosis I. Both sister chromatids attach to microtubules emanating from the same spindle pole.
- Incomplete CDK inactivation between the two meiotic divisions inhibits DNA replication.

Perspectives for the Future

The remarkable pace of cell cycle research over the last 25 years has led to a detailed model of eukaryotic cell cycle control. A beautiful logic underlies these molecular controls. Each regulatory event has two important functions: to activate a step of the cell cycle and to prepare the cell for the next event of the cycle. This strategy ensures that the phases of the cycle occur in the proper order.

Although the general logic of cell cycle regulation now seems well established, many critical details remain to be discovered. For instance, how cell growth and division are coordinated and how the metabolic state of a cell feeds into its cell cycle machinery remain to be discovered. A number of key nutrient and growth-factor-sensing pathways such as the AMPK, Ras, and TOR pathways have been identified and their inner workings recently revealed. Understanding how they impact the cell cycle machinery will be a critical question to be addressed in the years to come. Substantial progress has been made recently in identifying substrates phosphorylated by different CDKs, but much work remains to be done to understand how the modification of these proteins leads to the multiple events that these CDKs trigger.

Much has been discovered recently about the operation of cell cycle checkpoint pathways, but the mechanisms that activate ATM and ATR in the DNA damage checkpoint are poorly understood. Likewise, much remains to be learned about the control and mechanism of regulation of Mad2 in

the spindle assembly checkpoint. Many questions remain about how the plane of cytokinesis and the localization of daughter chromosomes are determined in cells that divide symmetrically and asymmetrically as is often seen as part of development of complex tissues and organ structures. How the cell cycle machinery is modulated by developmental cues to bring about specialized divisions is also an intense area of investigation.

Understanding these detailed aspects of cell cycle control will have significant consequences, particularly for the treatment of cancers. Cancer cells often have defects in cell cycle checkpoints that led to the accumulation of multiple mutations and DNA rearrangements that result in the cancer phenotype. However, the absence of these checkpoints can make specific types of cancers particularly vulnerable to extensive DNA damage induced with radiation therapy or chemotherapy. Normal cells activate cell cycle checkpoints that arrest the cell cycle until the DNA damage is repaired. But these cancer cells do not and as a consequence suffer sufficient genetic damage to induce apoptosis. If more were understood about cell cycle controls and checkpoint pathways, it might be possible to design ever more effective therapeutic strategies, especially against types of cancer that are largely resistant to today's conventional therapies. It seems very likely that better understanding of the molecular processes involved will allow the design of more effective treatments in the future.

Key Terms

anaphase-promoting complex/cyclosome (APC/C) 888	maturation-promoting factor (MPF) 880
APC/C specificity factor 888	meiosis 913
ATM/ATR 909	mitogen 892
Aurora B kinase 901	mitosis 875
Cdc14 phosphatase 913	mitotic CDKs 883
Cdc25 phosphatase 898	monopolin complex 918
CDK-activating kinases (CAK) 888	p53 protein 909
CDK inhibitor (CKIs) 888	Polo kinases 898
checkpoint pathway 874	Rb protein 891
cohesin 896	SCF (Skp1, Cullin, F-box proteins) 888
condensin 902	S phase CDKs 883
critical cell size 892	START 875
crossing over (or cross over) 915	securin 903
cyclin 874	sensor 906
cyclin-dependent kinase (CDK) 874	separase 903
E2F transcription factor 887	sister chromatids 875
G ₁ CDKs 883	synaptonemal complex 915
	Wee1 protein-tyrosine kinase 898

Review the Concepts

1. What cellular mechanism(s) ensure that passage through the cell cycle is unidirectional and irreversible? What molecular machinery underlies these mechanism(s)?
2. What types of experimental strategies do researchers employ to study cell cycle progression? How can these strategies differ based on genetic versus biochemical approaches?
3. Tim Hunt shared the 2001 Nobel Prize in Physiology or Medicine for his work in the discovery and characterization of cyclin proteins in eggs and embryos. Describe the experimental steps that led him to his discovery of cyclins.
4. What experimental evidence indicates that cyclin B is required for a cell to enter mitosis? What evidence indicates that cyclin B must be destroyed for a cell to exit mitosis?
5. What physiological differences between *S. pombe* and *S. cerevisiae* make them useful yet complementary tools for studying the molecular mechanisms involved in cell cycle regulation and control?
6. In *Xenopus*, one of the substrates of mitotic CDKs is the Cdc25 phosphatase. When phosphorylated by mitotic CDKs, Cdc25 is activated. What is the substrate of Cdc25? How does this information help to explain the rapid rise in mitotic CDK activity as cells enter mitosis?
7. Explain how CDK activity is modulated by the following proteins: (a) cyclin, (b) CAK, (c) Wee1, (d) p21.
8. Explain the role of CDK inhibitors. If cyclin-CDK complexes are required to allow regulated progression through the eukaryotic cell cycle, what would be the physiological rationale for CDK inhibitors?
9. What is the functional definition of START? Cancer cells typically lose START control. Explain how the following mutations, which are found in some cancer cells, lead to a bypass of START controls: (a) overexpression of cyclin D, (b) loss of Rb function, (c) loss of p16 function, (d) hyperactive E2F.
10. The Rb protein has been called the “master brake” of the cell cycle. Describe how the Rb protein acts as a cell cycle brake. How is the brake released in mid- to late G₁ to allow the cell to proceed to the S phase?
11. A common feature of cell cycle regulation is that the events of one phase ensure progression into a subsequent phase. In *S. cerevisiae*, G₁ and G₁/S phase CDKs promote S-phase entry. Name two ways in which they promote the activation of S phase.
12. For S phase to be completed in a timely manner, DNA replication initiates from multiple origins in eukaryotes. In *S. cerevisiae*, what role do S-phase CDKs and DDK complexes play to ensure that the entire genome is replicated once and only once per cell cycle?
13. In 2001, the Nobel Prize in Physiology or Medicine was awarded to three cell-cycle scientists. Paul Nurse was recognized for his studies with the fission yeast *S. pombe*, in particular for the discovery and characterization of the *wee1*[−]

gene. What did the characterization of the *wee1*[−] gene tell us about cell cycle control?

14. Describe how cells know whether sister kinetochores are properly attached to the mitotic spindle.
15. Describe the series of events by which the APC/C promotes the separation of sister chromatids at anaphase.
16. Meiosis and mitosis are overall analogous processes involving many of the same proteins. However, some proteins function uniquely in each of these cell-division events. Explain the meiosis-specific function of the following: (a) Ime2, (b) Rec8, (c) monopolin.
17. Leland Hartwell, the third recipient of the 2001 Nobel Prize in Physiology or Medicine, was acknowledged for his characterization of cell cycle checkpoint pathways in the budding yeast *S. cerevisiae*. What is a cell cycle checkpoint pathway? When during the cell cycle do checkpoint pathways function? How do cell cycle checkpoint pathways help to preserve the genome?
18. What role do tumor suppressors, including p53, play in mediating cell cycle arrest for cells with DNA damage?
19. Individuals with the hereditary disorder ataxia telangiectasia suffer from neurodegeneration, immunodeficiency, and increased incidence of cancer. The genetic basis for ataxia telangiectasia is a loss-of-function mutation in the ATM gene (*ATM* 5; *ataxia telangiectasia mutated*). Besides p53, what other substrate is phosphorylated by ATM? How does the phosphorylation of this substrate lead to inactivation of CDKs to enforce cell cycle arrest?

Analyze the Data

1. Many of the proteins that regulate transit through the cell cycle have been characterized. Xnf7, identified in extracts of *Xenopus* eggs, binds to the anaphase-promoting complex/cyclosome (APC/C). To elucidate the function of this protein, studies have been undertaken in which Xnf7 either has been depleted from extracts using an antibody raised against it or has been augmented in the extracts through addition of extra Xnf7. The consequences on transit through mitosis were then assessed (see J. B. Casaleto et al., 2005, *J. Cell Biol.* 169:61–71).

a. *Xenopus* egg extracts, arrested in metaphase, were either depleted of Xnf7 or were mock depleted (subjected to the same treatment as the first sample but without Xnf7 antibody), then released from metaphase arrest by addition of Ca²⁺. Aliquots of the extract were then sampled at various times after Ca²⁺ addition and the amounts of mitotic cyclin determined, as shown on the Western blot below. What information do these data provide about a possible function for Xnf7?

b. In additional studies, exogenous Xnf7 was added to *Xenopus* egg extracts, arrested at metaphase, so that the total amount of this protein in the extracts was higher than normal. The extracts, released from arrest by Ca^{2+} addition, were then assessed at various times after release for mitotic cyclin ubiquitinylation (cyclin-Ub conjugates). What is the rationale for examining ubiquitinylation? Using the following figure, determine what information these studies add beyond that obtained from part (a).

c. The spindle checkpoint pathway prevents cells with unattached kinetochores from proceeding into anaphase. Thus cells in which this checkpoint has been activated do not enter anaphase and do not degrade mitotic cyclin. Nocodazole, a drug that prevents microtubule assembly, can be used to activate the spindle checkpoint. Cells in nocodazole become arrested in early mitosis because they cannot form a spindle, and so all kinetochores remain unattached. To determine if Xnf7 is required for a functional spindle checkpoint, *Xenopus* egg extracts, arrested in metaphase, were subjected to various protocols (see the following figure): untreated (no nocodazole) or treated with nocodazole and either mock depleted (preimmune) or immunodepleted of Xnf7 (α -Xnf7). The extracts were then treated with Ca^{2+} to overcome arrest, and aliquots of the extracts were assessed at various times for mitotic cyclin, as shown on the Western blot below. What can you conclude about Xnf7 from these data?

2. In this chapter, we have discussed that cyclins are a required component of cyclin-CDK complexes for regulated progression through the eukaryotic cell cycle. Most cyclins are progressively synthesized and then degraded systematically in a temporal fashion at various points in the cell cycle. As we discussed in Chapter 7, cellular protein expression can be regulated at several different points starting with initiation of gene transcription.

a. What type of assay(s) could be employed to determine whether the expression of cyclin B is regulated at the transcriptional or translational level, if either?

b. Based on what you've learned in Chapter 19, is it possible that the activity of cyclin B could be regulated at the post-translational level? Describe a cellular mechanism through which this might happen.

c. How might it be possible for cyclin B expression and/or activity to be at least partially regulated by events in the cell's external environment?

Cell Biology Emerging from the Sea: The Discovery of Cyclins

T. Evans et al., 1983, *Cell* 33:391

From the first cell divisions after fertilization to aberrant divisions that occur in cancers, biologists have long been interested in how cells control when they divide. The processes of cell division have been separated into stages known collectively as the *cell cycle*. While studying early development in marine invertebrates in the early 1980s, Joan Ruderman and Tim Hunt discovered the cyclins, key regulators of the cell cycle.

Background

The question of how an organism develops from a fertilized egg continues to drive a large body of scientific research. Whereas such research was classically the concern of embryologists, the developing understanding of gene expression in the 1980s brought new approaches to answer this question. One such approach was to examine the pattern of gene expression in both the oocyte and the newly fertilized egg. Ruderman and Hunt were among the biologists who took this approach to the study of early development.

Biologists had well characterized the early development of a number of marine invertebrate systems. Their eggs are fertilized externally, allowing researchers to study their development in a plastic dish. During the early stages of development, the embryonic cells divide synchronously, which allows an entire population of cells to be studied at the same stage of the cell cycle. Researchers had established that a large part of the mRNA in the unfertilized oocyte is not translated. On fertilization, these maternal mRNA are rapidly translated. Previous studies had shown that when fertilized eggs are treated with drugs that inhibit protein synthesis, cell division could not take place. This suggested that the initial burst of protein synthesis from the maternal mRNA is required at the earliest

stages of development. Ruderman and Hunt, while teaching a physiology course at the Marine Biological Laboratory in Woods Hole, Massachusetts, began a set of experiments designed to uncover the genes that were expressed at this point as well as the mechanism by which this burst of protein synthesis was controlled.

The Experiment

In a collaborative project, Ruderman and Hunt looked at regulation of gene expression in the fertilized egg of the surf clam *Spisula solidissima*. Whereas it was known that overall protein synthesis rapidly increased on fertilization, they wanted to find out whether the proteins expressed in the earliest stage of development, the two-cell embryo, were different from those expressed in the unfertilized egg. When either eggs or two-cell clam embryos are treated with radioactively labeled amino acids, the cell takes up the amino acids, which are subsequently incorporated into newly synthesized proteins. Using this technique, Ruderman and Hunt monitored the pattern of protein synthesis by breaking open the cells, separating the proteins using SDS-polyacrylamide gel electrophoresis (SDS-PAGE), and then visualizing the radioactively labeled proteins by autoradiography. When they compared the pattern of protein synthesis in the egg with that in the two-cell embryo, they saw that three different proteins that were either not expressed or expressed at an extremely low levels in the egg were highly expressed in the embryo. In a subsequent study, Ruderman examined the pattern of protein expression in the oocytes of the starfish *Asterias forbesi* as they mature. She again observed the increased expression of three proteins of similar size to those that she and Hunt had seen in surf clam embryos.

Soon afterward, in a third study, Hunt examined the changes in protein expression during the maturation and fertilization of sea urchin oocytes. This time he performed the experiment in a slightly different manner. Rather than treating the oocytes and embryo with radioactively labeled amino acids for a set time period, he labeled the cells continuously for more than 2 hours, removing samples for analysis at 10-minute intervals. Now he could monitor the changes in protein expression throughout the early stages of development. As had been shown in other organisms, the pattern of protein synthesis was altered when the sea urchin oocyte was fertilized. Three proteins—represented by three prominent bands on an autoradiograph—were expressed in the embryos, but not in the oocytes. Interestingly, the intensity of one of these bands changed over time: the band was intense at the early time points, then barely visible after 85 minutes. It increased in intensity again between 95 and 105 minutes. The intensity of the band, representing the amount of the protein in the cell, appeared to be oscillating over time (Figure 1a). This suggested that the protein had been quickly degraded and then synthesized again.

Because the time frame of the experiment coincided with early embryonic cell divisions, Hunt next asked whether the synthesis and destruction of the protein was correlated with progression of the cell cycle. He examined a portion of cells from each time point under a microscope, counting the number of cells dividing at each time point where samples had been taken for protein analysis. Hunt then correlated the amount of the protein present in the cell with the proportion of cells dividing at each time point. He noticed that the level of expression of one of the proteins was highest before the cell divided and lowest on cell division

FIGURE 1 Autoradiography permits the detection of cyclical synthesis and destruction of mitotic cyclin in sea urchin embryos.

A suspension of sea urchin eggs was synchronously fertilized by the addition of sea urchin sperm, and ^{35}S -methionine was added. At 10-minute intervals beginning 26 minutes after fertilization, samples were taken for protein analysis on an SDS-polyacrylamide gel and for detection of cell cleavage by microscopy. (a) Autoradiogram of the SDS gel showing samples removed at each time point. Most proteins, such as B and C, continuously increased in intensity. In contrast, cyclin suddenly decreased in intensity at 76 minutes after fertilization and then began increasing again at 86 minutes. The cyclin band peaked again at 106 min and decreased again at 126 min. (b) Plot of the intensity of the cyclin band (red line) and the fraction of cells that had undergone cleavage during the previous 10-minute interval (cyan line). Note that the amount of cyclin fell precipitously just before cell cleavage. [From T. Evans et al., 1983, *Cell* **33**:389; courtesy of R. Timothy Hunt, Imperial Cancer Research Fund.]

(Figure 1b), suggesting a correlation with the stage of the cell cycle. When the same experiment was performed in the surf clam, Hunt saw that two of the proteins that he and Ruderman had described previously displayed the same pattern of synthesis and destruction. Hunt called these proteins *cyclins* to reflect their changing expression through the cell cycle.

Discussion

The discovery of the cyclins heralded an explosion of investigation into the cell cycle. It is now known that these

proteins regulate the cell cycle by associating with cyclin-dependent kinases, which in turn regulate the activities of a variety of transcription and replication factors, as well as other proteins involved in the complex alterations in cell architecture and chromosome structure that occur during mitosis. In brief, cyclin-CDK complexes direct and regulate progression through the cell cycle. As with so many key regulators of cellular functions, it was soon shown that the cyclins discovered in sea urchins and surf clams are conserved in eukaryotes from yeast to humans. Since the identification of

the first cyclins, scientists have identified at least 15 other cyclins that regulate all phases of the cell cycle.

In addition to the basic research interest in these proteins, the cyclins' central role in cell division has made them a focal point in cancer research. Cyclins are involved in the regulation of several genes that are known to play prominent roles in tumor development. Scientists have shown that at least one cyclin, cyclin D1, is overexpressed in a number of tumors. The role of these proteins in both normal and aberrant cell division continues to be an active and exciting area of research today.

Immunofluorescence micrograph of a section through the small intestine of a mouse in which the adhesion proteins Claudin-2 and Claudin-4 are stained red and green, respectively, and the nuclei of the cells are stained blue. The claudins are a family of tight junctional adhesion proteins that also define the selective permeability of pores through which small molecules and ions may move between the cells of an epithelium. Claudin-2 is expressed in the crypts (lower parts) of the intestinal epithelium and is thought to be involved in the transport of cations such as calcium. Claudin-4 is expressed only in the upper villus/surface region and is thought to function as a barrier to cation transport. [Image from Christoph Rahner, Yale School of Medicine, and J. M. Anderson, University of North Carolina.]

Integrating Cells Into Tissues

In the development of complex multicellular organisms such as plants and animals, progenitor cells differentiate into distinct “types” that have characteristic compositions, structures, and functions. Cells of a given type often aggregate into a *tissue* to cooperatively perform a common function: muscle contracts; nervous tissue conducts electrical impulses; xylem tissue in plants transports water. Different tissues can be organized into an *organ*, again to perform one or more specific functions. For instance, the muscles, valves, and blood vessels

of a heart work together to pump blood. The coordinated functioning of many types of cells and tissues permits the organism to move, metabolize, reproduce, and carry out other essential activities. Indeed, the complex and diverse morphologies of plants and animals are examples of the whole being greater than the sum of the individual parts, more technically described as the emergent properties of a complex system.

Vertebrates have hundreds of different cell types, including leukocytes (white blood cells) and erythrocytes (red blood

FIGURE 20-1 Overview of major cell-cell and cell-matrix adhesive interactions. Schematic cutaway drawing of a typical epithelial tissue, such as in the intestines. The apical (upper) surface of these cells is packed with fingerlike microvilli **1** that project into the intestinal lumen, and the basal (bottom) surface **2** rests on extracellular matrix (ECM). The ECM associated with epithelial cells is usually organized into various interconnected layers (e.g., the basal lamina, connecting fibers, connective tissue) in which large, interdigitating ECM macromolecules bind to one another and to the cells **3**. Cell-adhesion molecules (CAMs) bind to CAMs on other cells, mediating cell-cell adhesions **4**, and adhesion receptors bind to various components of the ECM, mediating cell-matrix adhesions **5**. Both types of cell-surface adhesion molecules are usually integral membrane proteins whose cytosolic domains often bind to multiple intracellular adapter proteins. These adapters, directly or indirectly, link the CAM to the cytoskeleton (actin or intermediate filaments) and to intracellular

signaling pathways. As a consequence, information can be transferred by CAMs and the macromolecules to which they bind from the cell exterior into the intracellular environment and vice versa. In some cases, a complex aggregate of CAMs, adapters, and associated proteins is assembled. Specific localized aggregates of CAMs or adhesion receptors form various types of cell junctions that play important roles in holding tissues together and facilitating communication between cells and their environment. Tight junctions **6**, lying just under the microvilli, prevent the diffusion of many substances through the extracellular spaces between the cells. Through connexon channels, gap junctions **7** allow the movement of small molecules and ions between the cytosols of adjacent cells. The remaining three types of junctions, adherens junctions **8**, spot desmosomes **9**, and hemidesmosomes **10**, link the cytoskeleton of a cell to other cells or to the ECM. [See V. Vasioukhin and E. Fuchs, 2001, *Curr. Opin. Cell Biol.* **13**:76.]

cells), photoreceptors in the retina, fat-storing adipocytes, fibroblasts in connective tissue, and hundreds of different subtypes of neurons in the human brain. Even simple animals exhibit complex tissue organization. The adult form of the roundworm *Caenorhabditis elegans* contains a mere 959 cells, yet these cells fall into 12 different general cell types and many distinct subtypes. Despite their diverse forms and functions, all animal cells can be classified as being components of just five main classes of tissue: *epithelial tissue*, *connective tissue*, *muscular tissue*, *nervous tissue*, and *blood*. Various cell types are arranged in precise patterns of staggering complexity to generate tissues and organs. The costs of such complexity include increased requirements for information, material, energy, and time during the development of an individual

organism. Although the physiological costs of complex tissues and organs are high, they confer the ability to thrive in varied and variable environments—a major evolutionary advantage.

One of the defining characteristics of animals with complex tissues and organs (metazoans) such as ourselves is that the external and internal surfaces of most of their tissues and organs, and indeed the exterior of the entire organism, are built from tightly packed sheet-like layers of cells known as **epithelia**. The formation of an epithelium and its subsequent remodeling into more complex collections of epithelial and nonepithelial tissues is a hallmark of the development of metazoans. Sheets of tightly attached epithelial cells act as regulatable, selective permeability barriers, which permit the generation of chemically and functionally distinct compartments in an organism, such as the

stomach and bloodstream. As a result, distinct and sometimes opposite functions (e.g., digestion and synthesis) can efficiently proceed simultaneously within an organism. Such compartmentalization also permits more sophisticated regulation of diverse biological functions. In many ways, the roles of complex tissues and organs in an organism are analogous to those of organelles and membranes in individual cells.

The assembly of distinct tissues and their organization into organs are determined by molecular interactions at the cellular level (Figure 20-1) and would not be possible without the temporally, spatially, and functionally regulated expression of a wide array of adhesive molecules. Cells in tissues can adhere directly to one another (*cell-cell adhesion*) through specialized membrane proteins called **cell-adhesion molecules (CAMs)** that often cluster into specialized cell junctions. In the fruit fly *Drosophila melanogaster*, at least 500 genes (~4 percent of the total) are estimated to be involved in cell adhesion. Cells in animal tissues also adhere indirectly (*cell-matrix adhesion*) through the binding of **adhesion receptors** in the plasma membrane to components of the surrounding **extracellular matrix (ECM)**, a complex interdigitating meshwork of proteins and polysaccharides secreted by cells into the spaces between them. Some adhesion receptors can also function as CAMs, mediating direct interaction between cells.

Cell-cell and cell-matrix adhesions not only allow cells to aggregate into distinct tissues but also provide a means for the bidirectional transfer of information between the exterior and the interior of cells. As we will see, both types of adhesions are intrinsically associated with the cytoskeleton and cellular signaling pathways. As a result, a cell's surroundings influence its shape and functional properties ("outside-in" effects); likewise, cellular shape and function influence a cell's surroundings ("inside-out" effects). Thus *connectivity* and *communication* are intimately related properties of cells in tissues. Such information transfer is important to many biological processes, including cell survival, proliferation, differentiation, and migration. Therefore it is not surprising that defects that interfere with adhesive interactions and the associated flow of information can cause or contribute to diseases, including a wide variety of neuromuscular and skeletal disorders and cancer.

In this chapter, we examine various types of adhesive molecules found on the surfaces of cells and in the surrounding extracellular matrix. Interactions between these molecules allow organization of cells into tissues and have profound impacts on tissue development, function, and pathology. Many adhesion molecules are members of families or superfamilies of related proteins. While each individual adhesion molecule performs a distinct role, we will focus on the common features shared by members of some of these families to illustrate the general principles underlying their structures and functions. Because of the particularly well-understood nature of the adhesive molecules in tissues that form tight epithelia, as well as their very early evolutionary development, we will initially focus on epithelial tissues, such as the walls of the intestinal tract and those that form skin. Epithelial cells are normally nonmotile (sessile); however, during development, wound healing, and in certain pathologic states (e.g., cancer), epithe-

lial cells can transform into more motile cells. Changes in expression and function of adhesive molecules play a key role in this transformation, as they do in normal biological processes involving cell movement, such as the crawling of white blood cells into sites of infection. We therefore follow the discussion of epithelial tissues with a discussion of adhesion in nonepithelial, developing, and motile tissues.

The evolution of plants and animals diverged before multicellular organisms arose. Thus multicellularity and the molecular means for assembling tissues and organs must have arisen independently in animal and plant lineages. Not surprisingly, then, animals and plants exhibit many differences in the organization and development of tissues. For this reason, we first consider the organization of tissues in animals and then deal separately with plants.

20.1 Cell-Cell and Cell-Matrix Adhesion: An Overview

There are many different types of cells in the body that dynamically interact with each other in a myriad of ways. These interactions, achieved via adhesion molecules, must be precisely and carefully controlled in time and space to correctly determine the structures and functions of tissues in a complex organism. It is not surprising, therefore, that cell-cell and cell-ECM adhesion molecules exhibit diverse structures and their expression levels vary in different cells and tissues. As a consequence, they mediate both the very specific and distinctive cell-cell and cell-ECM interactions that hold tissues together, as well as essential communication between cells and their environment. We begin this overview with a brief orientation to the various types of adhesive molecules present on cells and within the extracellular matrix, their major functions in organisms, and their evolutionary origin. In subsequent sections, we examine in detail the unique structures and properties of the various participants in cell-cell and cell-matrix interactions.

Cell-Adhesion Molecules Bind to One Another and to Intracellular Proteins

Cell-cell adhesion is mediated through membrane proteins called **cell-adhesion molecules (CAMs)**. Most CAMs fall into four major families: the cadherins, immunoglobulin (Ig) superfamily, integrins, and selectins. As the schematic structures in Figure 20-2 illustrate, CAMs are often mosaics of multiple distinct domains, many of which can be found in more than one kind of protein. Some of these domains confer the binding specificity that characterizes a particular protein. Other membrane proteins, whose structures do not belong to any of the major classes of CAMs, also participate in cell-cell adhesion in various tissues. As we will see later, integrins can function both as CAMs and, as depicted in Figure 20-2, adhesion receptors that bind to ECM components. Some Ig-superfamily CAMs can play this dual role as well.

FIGURE 20-2 Major families of cell-adhesion molecules (CAMs) and adhesion receptors. Dimeric E-cadherins most commonly form homophilic (self) cross-bridges with E-cadherins on adjacent cells. Members of the immunoglobulin (Ig) superfamily of CAMs can function as adhesion receptors or as CAMs that form both homophilic linkages (shown here) and heterophilic (nonself) linkages. Heterodimeric integrins (for example, α v and β 3 chains) function as CAMs or as adhesion receptors (shown here) that bind to very large, multi-adhesive matrix proteins such as fibronectin, only a small part of which is shown here.

Selectins, shown as dimers, contain a carbohydrate-binding lectin domain that recognizes specialized sugar structures on glycoproteins (shown here) or glycolipids on adjacent cells. Note that CAMs often form higher-order oligomers within the plane of the plasma membrane. Many adhesive molecules contain multiple distinct domains, some of which are found in more than one kind of CAM. The cytoplasmic domains of these proteins are often associated with adapter proteins that link them to the cytoskeleton or to signaling pathways. [See R. O. Hynes, 1999, *Trends Cell Biol.* 9(12):M33, and R. O. Hynes, 2002, *Cell* 110:673–687.]

CAMs mediate, through their extracellular domains, adhesive interactions between cells of the same type (*homotypic* adhesion) or between cells of different types (*heterotypic* adhesion). A CAM on one cell can directly bind to the same kind of CAM on an adjacent cell (*homophilic* binding) or to a different class of CAM (*heterophilic* binding). CAMs can be broadly distributed along the regions of plasma membranes that contact other cells or clustered in discrete patches or spots called **cell junctions**. Cell-cell adhesions can be tight and long lasting or relatively weak and transient. For example, the associations between nerve cells in the spinal cord or the metabolic cells in the liver exhibit tight adhesion. In contrast, immune-system cells in the blood often exhibit only weak, short-lasting interactions, allowing them to roll along and pass through a blood vessel wall on their way to fight an infection within a tissue.

The cytosol-facing domains of CAMs recruit sets of multifunctional **adapter proteins** (see Figure 20-1). These adapters act as linkers that directly or indirectly connect CAMs to elements of the cytoskeleton (see Chapters 17 and 18); they can also recruit intracellular molecules that function in signaling pathways to control gene expression and the activity of the CAMs themselves or other intracellular proteins (see

Chapters 15 and 16). In many cases, a complex aggregate of CAMs, adapter proteins, and other associated proteins is assembled at the inner surface of the plasma membrane. These complexes facilitate two-way “outside-in” and “inside-out” communication between cells and their surroundings.

The formation of many cell-cell adhesions often entails two types of molecular interactions (Figure 20-3). First, CAM monomers on one cell can bind to the same or different CAMs on an adjacent cell; these interactions are called *intercellular*, *adhesive*, or *trans* interactions. Second, monomeric CAMs on one cell may cluster together in the cell’s plasma membrane, forming homodimers or higher-order oligomers through their extracellular domains, cytosolic domains, or both; these interactions are called *intracellular*, *lateral*, or *cis* interactions. The lateral monomer clustering in one cell may increase the probability of monomer-to-monomer or oligomer-to-oligomer *trans* interactions with clustered CAMs on an adjacent cell. In addition, formation of monomer-to-monomer *trans* interactions can induce lateral clustering that strengthens the adhesive interactions. In many cases, the type of initial interaction—*trans* or *cis*—that leads to adhesion has not been established. In the case of the CAM called

FIGURE 20-3 Model for the generation of cell-cell adhesions.

Lateral interactions between cell-adhesion molecules (CAMs) within the plasma membrane of a cell can form clusters of monomers (*top left*) or directly bound dimers and larger oligomers (*bottom left*). The parts of the molecules that participate in these cis interactions vary among the

different CAMs. Subsequent trans interactions between distal domains of CAMs on adjacent cells—monomer-to-monomer trans interactions (*top right*) or oligomer-to-oligomer trans interactions (*bottom right*)—generate a strong, Velcro-like adhesion between the cells. [Adapted from M. S. Steinberg and P. M. McNutt, 1999, *Curr. Opin. Cell Biol.* 11:554.]

E-cadherin, biophysical studies suggest that formation of relatively weak monomer-to-monomer trans interactions may precede lateral clustering that strengthens the adhesion.

Adhesive interactions between cells vary considerably, depending on the tissue and the particular CAMs participating. Just like Velcro, very tight adhesion can be generated when many weak interactions are combined, and this is especially the case when CAMs are concentrated in small, well-defined areas such as cellular junctions. Some CAMs require calcium ions to form effective adhesions; others do not. Furthermore, the association of intracellular molecules with the cytosolic domains of CAMs can dramatically influence the intermolecular interactions of CAMs by promoting their cis association (clustering) or by altering their conformation. Among the many variables that determine the nature of adhesion between two cells are the binding affinity of the interacting molecules (thermodynamic properties), the overall “on” and “off” rates of association and dissociation

for each interacting molecule (kinetic properties), the spatial distribution or density of adhesion molecules (ensemble properties), the active versus inactive states of CAMs with respect to adhesion (biochemical properties), and external forces such as stretching and pulling in muscle or the laminar and turbulent flow of cells and surrounding fluids in the circulatory system (mechanical properties).

The Extracellular Matrix Participates in Adhesion, Signaling, and Other Functions

The extracellular matrix (ECM) is a complex combination of secreted proteins that is involved in holding cells and tissues together. The composition and physical properties of the ECM, which can vary depending on the tissue type, its location, and its physiologic state, can be sensed by cell-adhesion receptors that then instruct cells to behave appropriately in response to their environments. Just as the expression of specific

TABLE 20-1 Extracellular Matrix Proteins

adhesion molecules at the cell surface is tightly regulated, the composition of the ECM is carefully controlled.

The components of the extracellular matrix form a network by binding to each other and communicating with cells by binding to **adhesion receptors** on the cell surface. As a consequence of ECM interactions with receptors on adjacent cells, the ECM mediates indirect cell adhesion. ECM components include proteoglycans, a unique type of glycoprotein (a protein with covalently attached sugars); collagens, proteins that often form fibers; soluble multi-adhesive matrix proteins; and others (Table 20-1). Multi-adhesive matrix proteins, such as the proteins fibronectin and laminin, are long, flexible molecules that contain multiple domains. They are responsible for binding various types of collagen, other matrix proteins, polysaccharides, cell-surface adhesion receptors, and extracellular signaling molecules. These proteins are important organizers of the extracellular matrix. Through their interactions with adhesion receptors, they also regulate cell-matrix adhesion—and thus cell migration and cell shape.

The relative volumes of cells and their surrounding matrix vary greatly among different animal tissues. Some connective tissue, for instance, is mostly matrix, whereas many tissues such as epithelia are composed of very densely packed cells with relatively little matrix (Figure 20-4). The density of packing of the molecules within the ECM itself can also vary greatly.

H. V. Wilson's classic studies of adhesion in marine sponge cells showed conclusively that one primary function of ECM is

to literally hold tissue together. Figures 20-5a and 20-5b, which re-create Wilson's classic work, show that when sponges are mechanically dissociated and individual cells from two species of sponge are mixed, the cells of one species will adhere to each other but not to those from the other species.

(a) Connective tissue

(b) Tightly packed epithelial cells

FIGURE 20-4 Variation in the relative density of cells and ECM in different tissues. (a) Dense connective tissue contains mostly matrix of tightly packed ECM fibers (pink) interspersed by rows of relatively sparse fibroblasts, the cells that synthesized this ECM (purple).

(b) Squamous epithelium viewed from the top, showing epithelial cells tightly packed into a quilt-like pattern with the plasma membranes of adjacent cells close to one another and little ECM between the cells (see also Figure 20-9b). [(a) from Biophoto Associates (b) from Science Photo Library.]

EXPERIMENTAL FIGURE 20-5 Mechanically separated marine sponges reassemble through species-specific homotypic cell adhesion. (a) Two sponges, *Microciona prolifera* (orange) and *Halichondria panicea* (yellow), growing in the wild. (b) After mechanical disruption and mixing of both types of intact sponges, the individual cells were allowed to reassociate for ~30 minutes with gentle stirring. The cells aggregate with species-specific homotypic adhesion, forming micro-clumps of *Microciona prolifera* cells (orange) and *Halichondria panicea* cells (yellow). (c) and (d) Red or green fluorescently labeled beads were coated with the proteoglycan aggregation factor (AF) from

the ECM of either *Microciona prolifera* (MAF) or *Halichondria panicea* (HAF). Panel (c) shows that when both colored beads were coated only with MAF, they all aggregated together, forming yellow aggregates (combination of red and green). Panel (d) shows that MAF (red) and HAF (green) coated beads do not readily form mixed aggregates but rather assemble into distinct clumps held together by homotypic adhesion. (magnification, 40x) [Adapted from X. Fernandez-Busquets and M. M. Burger, 2003, *Cell Mol. Life Sci.* **60**:88–112, and J. Jarchow and M. M. Burger, 1998, *Cell Adhes. Commun.* **6**:405–414.]

This specificity is due, in part, to different adhesive proteins in the ECM that bind to the cells via surface receptors. These adhesive proteins can be purified and used to coat colored beads, which, when mixed, aggregate with each other with a specificity similar to that of intact sponge cells (Figure 20-5c, d).

The ECM plays a multitude of other roles in addition to facilitating cell adhesion. Different combinations of ECM components tailor the extracellular matrix for specific purposes at different anatomical sites: strength in a tendon, tooth, or bone; cushioning in cartilage; and adhesion in most tissues. The composition of the matrix also provides positional information for cells, letting a cell know where it is and what it should do. Changes in ECM components, which are constantly being remodeled, degraded, and resynthesized locally, can modulate the interactions of a cell with its environment. Furthermore, the matrix serves as a reservoir for many extracellular signaling molecules that control cell growth and differentiation. In addition, the matrix provides a lattice through or on which cells can move, particularly in the early stages of tissue assembly. Morphogenesis—the stage of embryonic development in which tissues, organs, and body parts are formed by cell movements and rearrangements—is critically dependent on cell-matrix adhesion as well as cell-cell adhesion. For example, cell-matrix interactions are required for branching morphogenesis (formation of branching structures) to form blood vessels, the air sacs in the lung, mammary and salivary glands, and other structures (Figure 20-6).

Disruptions in cell-matrix and cell-cell interactions can have devastating consequences for the development of tissues. Figure 20-7 shows the dramatic changes in the skeletal system of embryonic mice when the genes for either of two key ECM molecules, collagen II or perlecan, are inactivated. Disruptions in adhesion also are characteristic of various diseases, such as metastatic cancer, in which cancerous cells leave their normal locations and spread throughout the body.

EXPERIMENTAL FIGURE 20-6 Antibodies to fibronectin block branching morphogenesis in developing mouse tissues. Immature salivary glands were isolated from murine embryos and allowed to undergo branching morphogenesis in vitro for 10 hours in the absence (a) or presence (b) of an antibody that binds to and blocks the activity of the ECM molecule fibronectin. Anti-fibronectin antibody (Anti-FN) treatment blocked branch formation (arrowheads). Inhibition of fibronectin's adhesion receptor (an integrin) also blocks branch formation (not shown). [Takayoshi et al., 2003, *Nature* **423**:876–881.]

EXPERIMENTAL FIGURE 20-7 Inactivating the genes for some ECM proteins results in defective skeletal development in mice.

These photographs show skeletons of normal (left), collagen II-deficient (center), or perlecan-deficient (right) murine embryos that were isolated and stained to visualize the cartilage (blue) and bone (red). Absence of these key ECM components leads to dwarfism, with many skeletal elements shortened and disfigured. [From E. Gustafsson et al., 2003, *Ann. NY Acad. Sci.* 995:140–150.]

Although many CAMs and adhesion receptors were initially identified and characterized because of their adhesive properties, they also play a major role in signaling, using many of the pathways discussed in Chapters 15 and 16. Figure 20-8 illustrates how one adhesion receptor, integrin,

physically and functionally interacts via adapters and signaling kinases with a broad array of intracellular signaling pathways to influence cell survival, gene transcription, cytoskeletal organization, cell motility, and cell proliferation. Conversely, changes in the activities of signaling pathways inside cells can influence the structures of CAMs and adhesion receptors and so modulate their ability to interact with other cells and with the ECM. Thus, outside-in and inside-out signaling involves numerous interconnected pathways.

The Evolution of Multifaceted Adhesion Molecules Made Possible the Evolution of Diverse Animal Tissues

Cell-cell and cell-matrix adhesions are responsible for the formation, composition, architecture, and function of animal tissues. Not surprisingly, some adhesion molecules are evolutionarily ancient and are among the most highly conserved proteins in multicellular organisms. Sponges, the most primitive multicellular organisms, express certain CAMs and multi-adhesive ECM molecules whose structures are strikingly similar to those of the corresponding human proteins. The evolution of organisms with complex tissues and organs (metazoans) has depended on the evolution of diverse adhesion molecules with novel properties and functions, whose levels of

FIGURE 20-8 Integrin adhesion receptor-mediated signaling pathways that control diverse cell functions. Binding of integrins to their ligands (outside-in signaling) induces conformational changes in their cytoplasmic domains, directly or indirectly altering their interactions with cytoplasmic proteins. These include adapter proteins (e.g., talins, kindlins, paxillin, vinculin) and signaling kinases (src-family kinases, focal adhesion kinase [FAK], integrin-linked kinase [ILK]) that transmit signals via diverse signaling pathways, thereby influencing cell proliferation, cell survival, cytoskeletal organization, cell migration, and gene transcription. Components of several signaling pathways, some of which are associated directly with the plasma membrane, are shown in green boxes. Many of the components of the pathways shown here are shared with other cell-surface-activated signaling pathways (e.g., receptor tyrosine kinases shown on the right) and are discussed in Chapters 15 and 16. In turn, intracellular signaling pathways can, via adapter proteins, modify the ability of integrins to bind to their extracellular ligands (inside-out signaling). [Modified from W. Guo and F. G. Giancotti, 2004, *Nat. Rev. Mol. Cell Biol.* 5:816–826, and R. O. Hynes, 2002, *Cell* 110:673–687.]

expression differ in different types of cells. Some CAMs and adhesion receptors (e.g., cadherins, integrins, and immunoglobulin-superfamily CAMs such as L1CAM) and ECM components (type IV collagen, laminin, nidogen/entactin, and perlecan-like proteoglycans) are highly conserved because they play crucial roles in many different organisms, whereas other adhesion molecules are less conserved. For example, fruit flies do not have certain types of collagen or the ECM protein fibronectin that play important roles in mammals. A common feature of adhesive proteins is repeating domains forming very large proteins. The overall length of these molecules, combined with their ability to bind numerous ligands via distinct functional domains, likely played a role in their evolution.

The diversity of adhesive molecules arises in large part from two phenomena that can generate numerous closely related proteins, called **isoforms**, that constitute a protein family. In some cases, the different members of a protein family are encoded by multiple genes that arose from a common ancestor by gene duplication and divergent evolution (see Chapter 6). In other cases, a single gene produces an RNA transcript that can undergo alternative splicing to yield multiple mRNAs, each encoding a distinct protein isoform (see Chapter 8). Both phenomena contribute to the diversity of some protein families such as the cadherins. Particular isoforms of an adhesive protein are often expressed in some cell types and tissues but not others.

KEY CONCEPTS of Section 20.1

Cell-Cell and Cell-Matrix Adhesion: An Overview

- Cell-cell and cell–extracellular matrix (ECM) interactions are critical for assembling cells into tissues, controlling cell shape and function, and determining the developmental fate of cells and tissues. Diseases may result from abnormalities in the structures or expression of adhesion molecules.
- Cell-adhesion molecules (CAMs) mediate direct cell-cell adhesions (homotypic and heterotypic), and cell-surface adhesion receptors mediate cell-matrix adhesions (see Figure 20-1). These interactions bind cells into tissues and facilitate communication between cells and their environments.
- The cytosolic domains of CAMs and adhesion receptors bind adapter proteins that mediate interaction with cytoskeletal fibers and intracellular signaling proteins.
- The major families of CAMs are the cadherins, selectins, Ig-superfamily CAMs, and integrins (see Figure 20-2). Members of the integrin and Ig-CAM superfamilies can also function as adhesion receptors.
- Tight cell-cell adhesions entail both *cis* (lateral or intracellular) oligomerization of CAMs and *trans* (intercellular) interaction of like (homophilic) or different (heterophilic) CAMs (see Figure 20-3). The combination of *cis* and *trans* interactions produces a Velcro-like adhesion between cells.

- The extracellular matrix (ECM) is a complex meshwork of proteins and polysaccharides that contributes to the structure and function of a tissue. The major classes of ECM molecules are proteoglycans, collagens, and multi-adhesive matrix proteins (fibronectin, laminin).

- The evolution of adhesion molecules with specialized structures and functions permits cells to assemble into diverse classes of tissues with varying functions.

20.2 Cell-Cell and Cell-ECM Junctions and Their Adhesion Molecules

Cells in epithelial and nonepithelial tissues use many, but not all, of the same cell-cell and cell-matrix adhesion molecules. Because of the relatively simple organization of epithelia, as well as their fundamental role in evolution and development, we begin our detailed discussion of adhesion with the epithelium. In this section we will focus on regions of the cell surface that contain clusters of adhesion molecules in discrete patches or spots called **anchoring junctions**, **tight junctions**, and **gap junctions**. Anchoring and tight junctions play critical roles in mediating cell-cell and cell-ECM adhesion, and all three types of junctions mediate intercellular and/or cell-ECM communication.

Epithelial Cells Have Distinct Apical, Lateral, and Basal Surfaces

Cells that form epithelial tissues are said to be **polarized** because their plasma membranes are organized into discrete regions. Typically, the distinct surfaces of a polarized epithelial cell are called the **apical** (top), **lateral** (side), and **basal** (base or bottom) surfaces (see Figure 20-1 and Figure 20-9). The area of the apical surface is often greatly expanded by the formation of microvilli. Adhesion molecules play essential roles in generating and maintaining these distinct surfaces.

Epithelia in different body locations have characteristic morphologies and functions (see Figure 20-9). Stratified (multi-layered) epithelia commonly serve as barriers and protective surfaces (e.g., the skin), whereas simple, single-layer epithelia often selectively move ions and small molecules from one side of the layer to the other. For instance, the simple columnar epithelium lining the stomach secretes hydrochloric acid into the lumen; a similar epithelium lining the small intestine transports products of digestion from the lumen of the intestine across the basolateral surface into the blood (see Figure 11-19).

In simple columnar epithelia, adhesive interactions between the lateral surfaces hold the cells together into a two-dimensional sheet, whereas those at the basal surface connect the cells to a specialized underlying extracellular matrix called the **basal lamina**. Often the basal and lateral surfaces are similar in composition and together are called the **basolateral surface**. The basolateral surfaces of most simple epithelia are

FIGURE 20-9 Principal types of epithelia. The apical, lateral, and basal surfaces of epithelial cells exhibit distinctive characteristics. Often the basal and lateral sides of cells are not distinguishable and are collectively known as the basolateral surface. (a) Simple columnar epithelia consist of elongated cells, including mucus-secreting cells (in the lining of the stomach and cervical tract) and absorptive cells (in the lining of the small intestine). (b) Simple squamous epithelia, composed of thin cells, line the blood vessels (endothelial cells/ endothelium) and many body cavities. (c) Transitional epithelia, composed of several layers of cells with different shapes, line certain cavities subject to expansion and contraction (e.g., the urinary bladder). (d) Stratified squamous (nonkeratinized) epithelia line surfaces such as the mouth and vagina; these linings resist abrasion and generally do not participate in the absorption or secretion of materials into or out of the cavity. The basal lamina, a thin fibrous network of collagen and other ECM components, supports all epithelia and connects them to the underlying connective tissue.

usually on the side of the cell closest to the blood vessels, whereas the apical surface is not in direct contact with other cells or the ECM. In animals with closed circulatory systems, blood flows through vessels whose inner lining is composed of flattened epithelial cells called endothelial cells. In general,

epithelial cells are sessile, immobile cells, in that adhesion molecules firmly and stably attach them to one another and their associated ECM. One especially important mechanism used to generate strong, stable adhesions is to concentrate subsets of these molecules into clusters called cell junctions.

Three Types of Junctions Mediate Many Cell-Cell and Cell-ECM Interactions

All epithelial cells in a sheet are connected to one another and the extracellular matrix by specialized junctions. Although hundreds of individual dispersed adhesion-molecule-mediated interactions are sufficient to cause cells to adhere, the clustered groups of adhesion molecules at cell junctions play special roles in imparting strength and rigidity to a tissue, transmitting information between the extracellular and the intracellular space, controlling the passage of ions and molecules across cell layers, and serving as conduits for the movement of ions and molecules from the cytoplasm of one cell to that of its immediate neighbor. Particularly important to epithelial sheets is the formation of junctions that help form tight seals between the cells and thus allow the sheet to serve as a barrier to the flow of molecules from one side of the sheet to the other.

Three major classes of animal cell junctions are prominent features of simple columnar epithelia (Figure 20-10 and Table 20-2). **Anchoring junctions** and **tight junctions** perform the key task of holding the tissue together. Tight junctions also control the flow of solutes through the extracellular spaces between the cells forming an epithelial sheet. Tight junctions are found primarily in epithelial cells, whereas anchoring junctions can be seen in both epithelial and nonepithelial cells. These junctions are organized into three parts: (1) adhesive proteins in the plasma membrane that connect one cell to another cell on the lateral surfaces (CAMs) or to the extracellular matrix on the basal surfaces (adhesion receptors); (2) adapter proteins, which connect the CAMs or adhesion receptors to cytoskeletal filaments and signaling molecules; and (3) the cytoskeletal filaments themselves. The third class of junctions, **gap junctions**, permits the rapid diffusion of small, water-soluble molecules between the cytoplasm of adjacent cells. Along with anchoring and tight junctions, gap junctions share the role of helping a cell communicate with its environment. However, they are structurally very different from anchoring junctions and tight junctions and do not play a key role in strengthening cell-cell and cell-ECM adhesions. Found in both epithelial and nonepithelial cells, gap junctions resemble cell-cell junctions in plants called plasmodesmata, which we discuss in Section 20.6.

Three types of anchoring junctions are present in cells. Two participate in cell-cell adhesion, whereas the third participates in cell-matrix adhesion. *Adherens junctions* connect the lateral membranes of adjacent epithelial cells and are usually located near the apical surface, just below the tight junctions (see Figure 20-10). A circumferential belt of actin and myosin filaments in a complex with the adherens junctions functions as a tension cable that can internally brace the cell and thereby control its shape. Epithelial and some

FIGURE 20-10 Principal types of cell junctions connecting the columnar epithelial cells lining the small intestine. (a) Schematic cutaway drawing of intestinal epithelial cells. The basal surface of the cells rests on a basal lamina, and the apical surface is packed with fingerlike microvilli that project into the intestinal lumen. Tight junctions, lying just under the microvilli, prevent the diffusion of many substances between the intestinal lumen and the blood through the

extracellular space between cells. Gap junctions allow the movement of small molecules and ions between the cytosols of adjacent cells. The remaining three types of junctions—adherens junctions, spot desmosomes, and hemidesmosomes—are critical to cell-cell and cell-matrix adhesion and signaling. (b) Electron micrograph of a thin section of intestinal epithelial cells, showing relative locations of the different junctions. [Part (b) C. Jacobson et al., 2001, *J. Cell Biol.* **152**:435–450.]

other types of cells, such as smooth muscle and heart cells, are also bound tightly together by *desmosomes*, snaplike points of contact sometimes called *spot desmosomes*. *Hemidesmosomes*, found mainly on the basal surface of epithelial cells, anchor an epithelium to components of the underlying extracellular matrix, much like nails holding down a carpet. Adherens junctions and desmosomes are found in many different types of cells; hemidesmosomes appear to be restricted to epithelial cells.

Bundles of intermediate filaments running parallel to the cell surface or through the cell interconnect spot desmosomes and hemidesmosomes, imparting shape and rigidity to the cell. This close interaction between these junctions and the cytoskeleton helps transmit shear forces from one region of a cell layer to the epithelium as a whole, providing strength and rigidity to the entire epithelial cell layer. Desmosomes and hemidesmosomes are especially important in maintaining the integrity of skin epithelia. For instance, mutations that interfere with hemidesmosomal anchoring in the skin can lead to blistering in which the epithelium becomes detached from its matrix foundation and extracellular fluid

accumulates at the basolateral surface, forcing the skin to balloon outward.

Cadherins Mediate Cell-Cell Adhesions in Adherens Junctions and Desmosomes

The primary CAMs in adherens junctions and desmosomes belong to the *cadherin* family. In vertebrates, this protein family of more than 100 members can be grouped into at least six subfamilies, including *classical cadherins* and *desmosomal cadherins*, which we will describe below. The diversity of cadherins arises from the presence of multiple cadherin genes and alternative RNA splicing. It is not surprising that there are many different types of cadherins in vertebrates, because many different types of cells in widely diverse tissues use these CAMs to mediate adhesion and communication. The brain expresses the largest number of different cadherins, presumably owing to the necessity of forming many specific cell-cell contacts to help establish its complex wiring pattern. Invertebrates, however, are able to function with fewer than 20 cadherins.

TABLE 20-2 Cell Junctions

Junction	Adhesion Type	Principal CAMs or Adhesion Receptors	Cytoskeletal Attachment	Function
Anchoring junctions				
1. Adherens junctions	Cell-cell	Cadherins	Actin filaments	Shape, tension, signaling
2. Desmosomes	Cell-cell	Desmosomal cadherins	Intermediate filaments	Strength, durability, signaling
3. Hemidesmosomes	Cell-matrix	Integrin ($\alpha 6 \beta 4$)	Intermediate filaments	Shape, rigidity, signaling
Tight junctions	Cell-cell	Occludin, claudin, JAMs	Actin filaments	Controlling solute flow, signaling
Gap junctions	Cell-cell	Connexins, innexins, pannexins	Possible indirect connections to cytoskeleton through adapters to other junctions	Communication; small-molecule transport between cells
Plasmodesmata (plants only)	Cell-cell	Undefined	Actin filaments	Communication; molecule transport between cells

Classical Cadherins The “classical” cadherins include E-, N-, and P-cadherins, named for the type of tissues in which they were initially identified (epithelial, neural, and placental). E- and N-cadherins are the most widely expressed, particularly during early differentiation. Sheets of polarized epithelial cells, such as those that line the small intestine or kidney tubules, contain abundant E-cadherin along their lateral surfaces. Although E-cadherin is concentrated in adherens junctions, it is present throughout the lateral surfaces, where it is thought to link adjacent cell membranes. The results of experiments with L cells, a line of cultured mouse fibroblasts, demonstrated that E-cadherins preferentially mediate homophilic interactions. L cells express no cadherins and adhere poorly to themselves or to other cells. When the E-cadherin gene was introduced into L cells, the engineered cadherin-expressing L cells were found to adhere preferentially to other cells expressing E-cadherin (Figure 20-11). These L cells expressing E-cadherin formed epithelial-like aggregates with one another and with epithelial cells isolated from lungs. Although most E-cadherins exhibit primarily homophilic binding, some mediate heterophilic interactions.

The adhesiveness of cadherins depends on the presence of extracellular Ca^{2+} , the property that gave rise to their name (*calcium adhering*). For example, the adhesion of L cells expressing E-cadherin is prevented when the cells are bathed in a solution that is low in Ca^{2+} (see Figure 20-11). Some adhesion molecules require some minimal amount of Ca^{2+} in the extracellular fluid to function properly, whereas other molecules such as IgCAMs are Ca^{2+} independent.

The role of E-cadherin in adhesion can also be demonstrated in experiments with cultured epithelial cells called *Madin-Darby canine kidney (MDCK)* cells (see Figure 9-4).

A green fluorescent-protein-labeled form of E-cadherin has been used in these cells to show that clusters of E-cadherin mediate the initial attachment and subsequent zippering up of the cells into sheets (Figure 20-12). In this experimental system, the addition of an antibody that binds to E-cadherin, preventing its homophilic interactions, blocks the Ca^{2+} -dependent attachment of MDCK cells to each other and the subsequent formation of intercellular adherens junctions.

Each classical cadherin contains a single transmembrane domain, a relatively short C-terminal cytosolic domain, and five extracellular “cadherin” domains (see Figure 20-2). The extracellular domains are necessary for Ca^{2+} binding and cadherin-mediated cell-cell adhesion. Cadherin-mediated ad-

EXPERIMENTAL FIGURE 20-11 E-cadherin mediates Ca^{2+} -dependent adhesion of L cells. Under standard cell culture conditions in the presence of calcium in the extracellular fluid, L cells do not aggregate into sheets (*left*). Introduction of a gene that causes the expression of E-cadherin in these cells results in their aggregation into epithelial-like clumps in the presence of calcium (*center*) but not in its absence (*right*). Bar, 60 μm . [From Cynthia L. Adams et al., 1998, *J. Cell Biol.* 142(4):1105–1119.]

EXPERIMENTAL FIGURE 20-12 E-cadherin mediates adhesive connections in cultured MDCK epithelial cells. An E-cadherin gene fused to green fluorescent protein (GFP) was introduced into cultured MDCK cells. The cells were then mixed together in a calcium-containing medium and the distribution of fluorescent E-cadherin was visualized over time (shown in hours). Clusters of E-cadherin mediate the initial attachment and subsequent zippering up of the epithelial cells and the formation of junctions (bicellular junctions are where two cells join and appear as lines; tricellular junctions are the sites of intersection of three cells). [From Cynthia L. Adams et al., 1998, *J. Cell Biol.* **142**:1105–1119.]

Time after mixing cells (h):

hesion entails both cis lateral clustering (intracellular) and trans adhesive (intercellular) molecular interactions (see Figure 20-3). The Ca^{2+} -binding sites, located between the cadherin repeats, may help stabilize cis or trans interactions. The cadherin clusters form intercellular complexes to generate cell-cell adhesion and then additional lateral contacts, resulting in a “zippering up” of cadherins into adhesive arrays. In this way, multiple low-affinity interactions sum to produce a very tight intercellular adhesion.

The results of domain swap experiments, in which an extracellular domain of one kind of cadherin is replaced with the corresponding domain of a different cadherin, have indicated that the specificity of binding resides, at least in part, in the most distal (farthest from the membrane) extracellular domain, the N-terminal domain. Cadherin-mediated trans adhesion is commonly thought to require only head-to-head interactions between the N-terminal domains of cadherin oligomers on adjacent cells, as depicted in Figure 20-13.

The C-terminal cytosolic domain of classical cadherins is linked to the actin cytoskeleton by adapter proteins (see Figure

20-13). These linkages are essential for strong adhesion, owing primarily to their contributing to increased lateral associations. For example, disruption of the interactions between classical cadherins and α - or β -catenin—two common adapter proteins that link classical cadherins to actin filaments—dramatically reduces cadherin-mediated cell-cell adhesion. This disruption occurs spontaneously in tumor cells, which sometimes fail to express α -catenin, and can be induced experimentally by depleting the cytosolic pool of accessible β -catenin. The cytosolic domains of cadherins also interact with intracellular signaling molecules such as p120-catenin. Interestingly, β -catenin plays a dual role: it not only mediates cytoskeletal attachment but also serves as a signaling molecule, translocating to the nucleus and altering gene transcription in the Wnt signaling pathway (see Figure 16-30).

Classical cadherins play a critical role during tissue differentiation. Each classical cadherin has a characteristic tissue distribution. In the course of differentiation, the amount or nature of the cell-surface cadherins changes, affecting many aspects of cell-cell adhesion and cell migration. For instance,

FIGURE 20-13 Protein constituents of typical adherens junctions. The exoplasmic domains of E-cadherin dimers clustered at adherens junctions on adjacent cells form Ca^{2+} -dependent homophilic interactions. The cytosolic domains of the E-cadherins bind directly or indirectly to multiple adapter proteins (e.g., β -catenin) that connect the junctions to actin filaments (F-actin) of the cytoskeleton and participate in intracellular signaling pathways. Somewhat different sets of adapter

proteins are illustrated in the two cells to emphasize that a variety of adapters can interact with adherens junctions. Some of these adapters, such as ZO1, can interact with several different CAMs. There is some controversy about whether α -catenin mediates cadherin/ β -catenin interaction with actin directly, via intermediate binding proteins (indicated in the figure by question marks) or via more complex mechanisms.

[Adapted from V. Vasioukhin and E. Fuchs, 2001, *Curr. Opin. Cell Biol.* **13**:76.]

the reorganization of tissues during morphogenesis is often accompanied by the conversion of nonmotile epithelial cells into motile precursor cells for other tissues (mesenchymal cells). Such *epithelial-mesenchymal transitions* are associated with a reduction in the expression of E-cadherin (Figure 20-14a, b). The conversion of epithelial cells into malignant carcinoma cells, such as in certain ductal breast tumors or hereditary diffuse gastric cancer (Figure 20-14c), is also marked by a loss of E-cadherin activity.

The firm epithelial cell-cell adhesions mediated by cadherins in adherens junctions permits the formation of a second class of intercellular junctions in epithelia—tight junctions, which we will turn to shortly.

Desmosomal Cadherins Desmosomes (Figure 20-15) contain two specialized cadherin proteins, *desmoglein* and

desmocollin, whose cytosolic domains are distinct from those in the classical cadherins. The cytosolic domains of desmosomal cadherins interact with adapter proteins such as plakoglobin (similar in structure to β -catenin), plakophilins, and a member of the plakin family of adapters called desmoplakin. These adapters, which form the thick cytoplasmic plaques characteristic of desmosomes, in turn interact with intermediate filaments.

The cadherin desmoglein was identified through studies of an unusual but revealing skin disease called *pemphigus vulgaris*, an autoimmune disease. Patients with autoimmune disorders synthesize self-attacking, or “auto,” antibodies that bind to a normal body protein. In pemphigus vulgaris the auto-antibodies disrupt adhesion between epithelial cells, causing blisters of the skin and mucous membranes. The predominant auto-antibody was shown to be specific for desmoglein; indeed, the addition of such antibodies to normal skin induces the formation of blisters and disruption of cell adhesion. ■

Integrins Mediate Cell-ECM Adhesions, Including Those in Epithelial Cell Hemidesmosomes

To be stably anchored to solid tissue and organs, simple columnar epithelial sheets must be firmly attached via their basal surfaces to the underlying extracellular matrix (basal lamina). This attachment occurs via adhesion receptors called **integrins** (see Figure 20-2), which are located both within and outside of anchoring junctions called *hemidesmosomes* (see Figure 20-10a). Hemidesmosomes comprise several integral membrane proteins linked via cytoplasmic adapter proteins (e.g., plakins) to keratin-based intermediate filaments. The principal ECM adhesion receptor in epithelial hemidesmosomes is integrin $\alpha 6 \beta 4$.

Integrins function as adhesion receptors and CAMs in a wide variety of epithelial and nonepithelial cells, mediating

many cell-matrix and cell-cell interactions (Table 20-3). In vertebrates, at least 24 integrin heterodimers, composed of 18 types of α subunits and eight types of β subunits in various combinations, are known. A single β chain can interact with any one of multiple α chains, forming integrins that bind different ligands. This phenomenon of *combinatorial diversity* allows a relatively small number of components to serve a large number of distinct functions. Although most cells express several distinct integrins that bind the same or different ligands, many integrins are expressed predominantly in certain types of cells. Not only do many integrins bind more than one ligand but several of their ligands bind to multiple integrins.

All integrins appear to have evolved from two ancient general subgroups: those that bind proteins containing the tripeptide sequence Arg-Gly-Asp, usually called the *RGD sequence* (fibronectin is one such protein), and those that bind laminin. Several integrin α subunits contain a distinctive inserted domain, the *I-domain*, which can mediate binding of certain integrins to various collagens in the ECM. Some integrins with I-domains are expressed exclusively on leukocytes (white blood cells) and red and white blood cell precursor (hematopoietic) cells. I-domains also recognize cell-adhesion molecules on other cells, including members of the Ig superfamily (e.g., ICAMs, VCAMs), and thus participate in cell-cell adhesion.

Integrins typically exhibit low affinities for their ligands, with dissociation constants K_d between 10^{-6} and 10^{-7} mol/L. However, the multiple weak interactions generated by the

TABLE 20-3 Selected Vertebrate Integrins*

Subunit Composition	Primary Cellular Distribution	Ligands
$\alpha 1 \beta 1$	Many types	Mainly collagens
$\alpha 2 \beta 1$	Many types	Mainly collagens; also laminins
$\alpha 3 \beta 1$	Many types	Laminins
$\alpha 4 \beta 1$	Hematopoietic cells	Fibronectin; VCAM-1
$\alpha 5 \beta 1$	Fibroblasts	Fibronectin
$\alpha 6 \beta 1$	Many types	Laminins
$\alpha L \beta 2$	T lymphocytes	ICAM-1, ICAM-2
$\alpha M \beta 2$	Monocytes	Serum proteins (e.g., C3b, fibrinogen, factor X); ICAM-1
$\alpha IIb \beta 3$	Platelets	Serum proteins (e.g., fibrinogen, von Willebrand factor, vitronectin); fibronectin
$\alpha 6 \beta 4$	Epithelial cells	Laminin

*The integrins are grouped into subfamilies having a common β subunit. Ligands shown in red are CAMs; all others are ECM or serum proteins. Some subunits can have multiple spliced isoforms with different cytosolic domains.

Tsukita et al., 2001, *Nat. Rev. Mol. Cell Biol.* **2**:285.]

binding of hundreds or thousands of integrin molecules to their ligands on cells or in the extracellular matrix allow a cell to remain firmly anchored to its ligand-expressing target.

Parts of both the α and the β subunits of an integrin molecule contribute to the primary extracellular ligand-binding site (see Figure 20-2). Ligand binding to integrins also requires the simultaneous binding of divalent cations. Like other cell-surface adhesive molecules, the cytosolic region of integrins interacts with adapter proteins that in turn bind to the cytoskeleton and intracellular signaling molecules. Most integrins are linked to the actin cytoskeleton, including two of the integrins that connect the basal surface of epithelial cells to the basal lamina via the ECM molecule laminin. However, some integrin heterodimers interact with intermediate filaments. The cytosolic domain of the $\beta 4$ chain in the $\alpha 6 \beta 4$ integrin in hemidesmosomes, which is much longer than the cytosolic domains of other β integrins, binds to specialized adapter proteins that in turn interact with keratin-based intermediate filaments (see Table 20-3).

As we will see, the diversity of integrins and their ECM ligands allows integrins to participate in a wide array of key biological processes, including the inflammatory response and the migration of cells to their correct locations in the formation of the body plan of an embryo (morphogenesis). The importance of integrins in diverse processes is highlighted by the defects exhibited by knockout mice engineered to have mutations in various integrin subunit genes. These defects include major abnormalities in development, blood vessel formation, leukocyte function, inflammation, bone remodeling, and hemostasis. Despite their differences, all these processes depend on integrin-mediated interactions between the cytoskeleton and either the ECM or CAMs on other cells.

In addition to their adhesion function, integrins can mediate outside-in and inside-out signaling (see Figure 20-8). The engagement of integrins by their extracellular ligands can, through adapter proteins bound to the integrin's cytosolic region, influence the cytoskeleton and intracellular signaling pathways (outside-in signaling). Conversely, intracellular signaling pathways can alter, from the cytoplasm, the structure of integrins and consequently their abilities to adhere to their extracellular ligands and mediate cell-cell and cell-matrix interactions (inside-out signaling). Integrin-mediated signaling pathways influence processes as diverse as cell survival, cell proliferation, and programmed cell death (see Chapter 21).

Tight Junctions Seal Off Body Cavities and Restrict Diffusion of Membrane Components

For polarized epithelial cells to function as barriers and mediators of selective transport, extracellular fluids surrounding their apical and basolateral membranes must be kept separate. Tight junctions between adjacent epithelial cells are usually located in a band surrounding the cell just below the apical surface and help establish and maintain cell polarity (Figures 20-10 and 20-16). These specialized junctions form a barrier that seals off body cavities such as the intestinal

lumen and separates the blood from the cerebral spinal fluid of the central nervous system (i.e., the blood-brain barrier).

Tight junctions prevent the diffusion of macromolecules and, to varying degrees, small water-soluble molecules and ions across an epithelial sheet via the spaces between cells. They also help maintain the polarity of epithelial cells by preventing the diffusion of membrane proteins and glycolipids between the apical and the basolateral regions of the plasma membrane, ensuring that these regions contain different membrane components. Indeed, the lipid compositions of the apical and basolateral regions of the exoplasmic leaflet are distinct. Essentially all glycolipids are restricted to the exoplasmic face of the apical membrane, as are all proteins linked to the membrane by a glycosylphosphatidylinositol (GPI) anchor (see Figure 10-19). In contrast, the apical and basolateral regions of the cytosolic leaflet have uniform membrane composition in epithelial cells; their lipids and proteins can apparently diffuse laterally from one region of the membrane to the other.

Tight junctions are composed of thin bands of plasma-membrane proteins that completely encircle the cell and are in contact with similar thin bands on adjacent cells. When thin sections of cells are viewed in an electron microscope, the lateral surfaces of adjacent cells appear to touch each other at intervals and even to fuse in the zone just below the apical surface (see Figure 20-10b). In freeze-fracture preparations, tight junctions appear as an interlocking network of ridges and grooves in the plasma membrane (Figure 20-16a). Very high magnification reveals that rows of protein particles 3–4 nm in diameter form the ridges seen in freeze-fracture micrographs of tight junctions. In the model shown in Figure 20-16b, the tight junction is formed by a double row of these particles, one row donated by each cell. Treatment of an epithelium with the protease trypsin destroys the tight junctions, supporting the proposal that proteins are essential structural components of these junctions.

The two principal integral membrane proteins found in tight junctions are *occludin* and *claudin* (from the Latin *claudere*, “to close”). When investigators engineered mice with mutations inactivating the occludin gene, which was thought to be essential for tight junction formation, the mice surprisingly still had morphologically distinct tight junctions. Further analysis led to the discovery of claudin. Each of these proteins has four membrane-spanning α helices (Figure 20-17). Another tight junction protein, *tricellulin*, also has this structure. Tricellulin is concentrated at junctions where three cells intersect (see Figure 20-12 and Figure 20-17). The claudin multi-gene family encodes at least 24 homologous proteins that exhibit distinct tissue-specific patterns of expression. A group of *junction adhesion molecules* (JAMs) have also been found to contribute to homophilic adhesion and other functions of tight junctions. JAMs and another junctional protein, the *cox-sackievirus and adenovirus receptor* (CAR), contain a single trans-membrane α helix and belong to the Ig superfamily of CAMs. The extracellular domains of rows of occludin, claudin, and JAM proteins in the plasma membrane of one cell apparently form extremely tight links with similar rows of the same proteins in an adjacent cell, creating a tight seal. Ca^{2+} -dependent

FIGURE 20-17 Proteins mediating tight junctions. As shown in these schematic drawings of the major proteins in tight junctions, both occludin and claudins contain four transmembrane helices, whereas the junction adhesion molecule (JAM) has a single transmembrane domain and a large extracellular region. The extracellular loop of the claudins that significantly contributes to paracellular ion selectivity is indicated by an asterisk. Inset: Immunofluorescence localization of occludin (green) and tricellulin (red) in mouse intestinal epithelium. Note how tricellulin is predominantly concentrated in tricellular junctions. Bar, 20 μm . [Bottom drawing adapted from S. Tsukita et al., 2001, *Nature Rev. Mol. Cell Biol.* 2:285. Inset from J. Ikenouchi et al., 2005, *J. Cell Biol.* 171:939–945. Tricellulin constitutes a novel barrier at tricellular contacts of epithelial cells.]

cadherin-mediated adhesion also plays an important role in tight junction formation, stability, and function.

The long C-terminal cytosolic segment of occludin binds to PDZ domains in some large cytosolic adapter proteins. *PDZ domains* are about 80 to 90 amino acids long and are found in various cytosolic proteins; they mediate binding to other cytosolic proteins or to the C-termini of particular plasma-membrane proteins. Cytosolic proteins containing a PDZ domain often have more than one of them. In the human genome, there are ~250 PDZ domains found in about 100 proteins. The multiple PDZ domain proteins can serve as scaffolds to assemble proteins into larger functional complexes. The PDZ-containing adapter proteins associated with occludin are bound, in turn, to other cytoskeletal and signaling proteins and to actin fibers. These interactions appear to stabilize the linkage between occludin and claudin molecules that is essential for maintaining the integrity of tight junctions. The C-termini of claudins also bind to the intracellular, multiple-PDZ-domain-containing adapter protein ZO-1, which is also found in adherens junctions (see Figure 20-13).

EXPERIMENTAL FIGURE 20-18 Tight junctions prevent passage of large molecules through extracellular space between epithelial cells. Tight junctions in the pancreas are impermeable to the large water-soluble colloid lanthanum hydroxide (dark stain) administered from the basolateral side of the epithelium. [Courtesy of D. Friend.]

Thus, as is the case for adherens junctions and desmosomes, cytosolic adapter proteins and their connections to the cytoskeleton are critical components of tight junctions.

A simple experiment demonstrates the impermeability of tight junctions to some water-soluble substances. In this experiment, lanthanum hydroxide (an electron-dense colloid of high molecular weight) is injected into the pancreatic blood vessel of an experimental animal; a few minutes later, the pancreatic epithelial acinar cells are fixed and prepared for microscopy. As shown in Figure 20-18, the lanthanum hydroxide diffuses from the blood into the space that separates the lateral surfaces of adjacent acinar cells but cannot penetrate past the tight junction.

As a consequence of tight junctions, movement of many nutrients across the intestinal epithelium cannot occur between cells and is in large part achieved through the *transcellular pathway* via specific membrane-bound transport proteins (see Figures 11-30 and 20-19). The barrier to diffusion provided by tight junctions, however, is not absolute, for they exhibit size- and ion-selective permeability. The importance of this selective permeability is highlighted by the evolutionary conservation of the molecules that establish it and diseases that arise when it is disrupted. For example, murine embryos cannot develop properly if this selective permeability is disrupted because fluid balance on distinct sides of epithelia cannot be maintained properly. Similarly, the kidneys depend on proper tight junctional permeability to establish the ion gradients necessary for normal regulation of body fluids and waste removal. Owing at least in part to the varying properties of the different types of claudin molecules located in different tight junctions, the permeability of the

FIGURE 20-19 Transcellular and paracellular pathways of transepithelial transport. Transcellular transport requires the cellular uptake of molecules on one side and subsequent release on the opposite side by mechanisms discussed in Chapter 11. In paracellular transport, molecules move extracellularly through parts of tight junctions, whose permeability to small molecules and ions depends on the composition of the junctional components and the physiologic state of the epithelial cells. [Adapted from S. Tsukita et al., 2001, *Nat. Rev. Mol. Cell Biol.* 2:285.]

tight junctions to ions, small molecules, and water varies enormously among different epithelial tissues. In epithelia with selectively permeable tight junctions, certain small molecules and ions can move from one side of the cell layer to the other through the *paracellular pathway* in addition to the transcellular pathway (Figure 20-19). One of the extracellular loops in the claudins (see Figure 20-17) is thought to play a major role in defining the selective permeability conferred on tight junctions by specific claudin isoforms.

The permeability of tight junctions can be altered by intracellular signaling pathways, especially G protein and cyclic AMP-coupled pathways (see Chapter 15). The regulation of tight junction permeability is often studied by measuring ion flux (electrical resistance) or the movement of radioactive or fluorescent molecules across monolayers of MDCK or other epithelial cells (transepithelial resistance).

 The importance of paracellular transport is apparent in several human diseases. In hereditary hypomagnesemia, defects in the *claudin16* gene prevent the normal paracellular flow of magnesium in the kidney. This results in an abnormally low blood level of magnesium, which can lead to convulsions. Furthermore, a mutation in the *claudin14* gene causes hereditary deafness, apparently by altering transport around hair-cell epithelia in the cochlea of the inner ear.

Some pathogens have evolved to exploit the molecules in tight junctions. Some use junctional proteins as co-receptors to initially attach to cells prior to infecting them (e.g., hepatitis C virus uses *claudin1* and *occludin*, together with two other “co-receptors,” to enter liver cells). Others break down the junctional barrier and cross epithelia via paracellular movement, and others produce toxins that alter barrier function (either from the extracellular or intracellular spaces). For example, toxins produced by *Vibrio cholerae*, the enteric bacteria that causes cholera, alter the permeability barrier of the

intestinal epithelium by altering the composition or activity of tight junctions. *Vibrio cholerae* also releases a protease that disrupts tight junctions by degrading the extracellular part of occludin. Other bacterial toxins can affect the ion-pumping activity of membrane transport proteins in intestinal epithelial cells. Toxin-induced changes in tight junction permeability (increased paracellular transport) and in protein-mediated ion pumping (increased transcellular transport) can result in massive loss of internal body ions and water into the gastrointestinal tract, which in turn leads to diarrhea and potentially lethal dehydration (see Chapter 11). ■

Gap Junctions Composed of Connexins Allow Small Molecules to Pass Directly Between Adjacent Cells

Early electron micrographs of cells in tissues revealed sites of cell-cell contact with a characteristic intercellular gap (Figure 20-20a). This feature was found in virtually all contacting animal cells and prompted early morphologists to call these regions gap junctions. In retrospect, the most important feature of these junctions is not the ~2–4-nm gap itself but a well-defined set of cylindrical particles that cross the gap and compose pores connecting the cytoplasms of adjacent cells.

In many tissues, anywhere from a few to thousands of gap junctional particles cluster together in patches (e.g., along the lateral surfaces of epithelial cells; see Figure 20-10). When the plasma membrane is purified and then sheared into small fragments, some pieces mainly containing patches of gap junctions are generated. Owing to their relatively high protein content, these fragments have a higher density than that of the bulk of the plasma membrane and can be purified by equilibrium density-gradient centrifugation (see Figure 9-26). When these preparations are viewed perpendicular to the membrane, the gap junctions appear as arrays of hexagonal particles that enclose water-filled channels (Figure 20-20b).

The effective pore size of gap junctions can be measured by injecting a cell with a fluorescent dye covalently linked to membrane bilayer impermeable molecules of various sizes and observing with a fluorescence microscope whether the dye passes into neighboring cells. Gap junctions between mammalian cells permit the passage of molecules as large as 1.2 nm in diameter. In insects, these junctions are permeable to molecules as large as 2 nm in diameter. Generally speaking, molecules smaller than 1200 Da pass freely and those larger than 2000 Da do not pass; the passage of intermediate-size molecules is variable and limited. Thus ions, many low-molecular-weight precursors of cellular macromolecules, products of intermediary metabolism, and small intracellular signaling molecules can pass from cell to cell through gap junctions.

In nervous tissue, some neurons are connected by gap junctions through which ions pass rapidly, thereby allowing very rapid transmission of electric signals. Impulse transmission through these connections, called electrical synapses, is

almost a thousandfold as rapid as at chemical synapses (see Chapter 22). Gap junctions are also present in many non-neuronal tissues, where they help to integrate the electrical and metabolic activities of many cells. In the heart, for instance, gap junctions rapidly pass ionic signals among muscle cells, which are tightly interconnected via desmosomes, and thus contribute to the electrically stimulated coordinate contraction of cardiac muscle cells during a beat. As discussed in Chapter 15, some extracellular hormonal signals induce the production or release of small intracellular signaling molecules called **second messengers** (e.g., cyclic AMP, IP₃, and Ca²⁺) that regulate cellular metabolism. Because second messengers can be transferred between cells through gap junctions, hormonal stimulation of one cell can trigger a coordinated response by that same cell as well as many of its neighbors. Such gap-junction-mediated signaling plays an important role, for example, in the secretion of digestive enzymes by the pancreas and in the coordinated muscular contractile waves (peristalsis) in the intestine. Another vivid example of gap-junction-mediated transport is the phenomenon of *metabolic coupling*, or *metabolic cooperation*, in which a cell transfers nutrients or intermediary metabolites to a neighboring cell that is itself unable to synthesize them. Gap junctions play critical roles in the development of egg cells in the ovary by mediating the movement of both metabolites and signaling molecules between an oocyte and its surrounding granulosa cells as well as between neighboring granulosa cells.

A current model of the structure of the gap junction is shown in Figure 20-20c, d, e. Vertebrate gap junctions are composed of **connexins**, a family of structurally related transmembrane proteins with molecular weights between 26,000 and 60,000. A completely different family of proteins, the **innexins**, forms the gap junctions in invertebrates. A third family of innexin-like proteins, called **pannexins**, has been found in both vertebrates and invertebrates. Each vertebrate hexagonal particle consists of 12 noncovalently associated connexin molecules: six form a cylindrical connexon hemichannel in one plasma membrane that is joined to a connexon hemichannel in the adjacent cell membrane, forming the continuous aqueous channel (diameter ~14 Å) between the cells. Each individual connexin molecule has four membrane-spanning α -helices with a topology similar to that of occludin (see Figure 20-17), resulting in 24 transmembrane α -helices in each hemichannel. Pannexins are capable of forming intercellular channels as well; however, pannexin hemichannels may also function to permit direct exchange between the intracellular and extracellular spaces.

There are 21 different connexin genes in humans, with different sets of connexins expressed in different cell types. This diversity, together with the generation of mutant mice with inactivating mutations in connexin genes, has highlighted the importance of connexins in a wide variety of cellular systems. Some cells express a single connexin that forms homotypic channels. Most cells, however, express at least two connexins; these different proteins assemble into heteromeric connexon, which in turn form heterotypic gap junction channels. Diversity in channel composition leads to differences in

FIGURE 20-20 Gap junctions. (a) In this thin section through a gap junction connecting two mouse liver cells, the two plasma membranes are closely associated for a distance of several hundred nanometers, separated by a “gap” of 2–3 nm. (b) Numerous roughly hexagonal particles are visible in this perpendicular view of the cytosolic face of a region of plasma membrane enriched in gap junctions. Each particle aligns with a similar particle on an adjacent cell, forming a channel connecting the two cells. (c) Schematic model of a gap junction connecting two plasma membranes. Both membranes contain connexon hemichannels, cylinders of six dumbbell-shaped connexin molecules. Two connexons join in the gap between the cells to form a gap-junction channel, 1.5–2.0 nm in diameter, that connects the cytosols of the two cells. (d) Model of recombinant human Cx26 gap

junction connexon channel determined by x-ray crystallography (3.5-Å resolution). (Left) Space filling model of a side view of the complete structure of two attached hemichannels oriented as in part (c). Each of the six connexins that comprise a connexon hemichannel has four transmembrane helices and a distinct color. The structures of the loops connecting the transmembrane helices are not well defined and not shown. (Right) View from the cytosol perpendicular to the membrane bilayers, looking down on the connexon with its central pore. The diameter of the pore’s channel is ~14 Å and it is lined by many polar/charged amino acids. [Part (a) courtesy of D. Goodenough; part (b) courtesy of N. Gilula; part (d) adapted from S. Nakagawa et al., 2010, *Curr. Opin. Struct. Biol.* **20**(4):423–430.]

channel permeability. For example, channels made from a 43-kDa connexin isoform, Cx43—the most ubiquitously expressed connexin—are more than 100-fold as permeable to ADP and ATP as those made from Cx32 (32 kDa).

The permeability of gap junctions is regulated by post-translational modification of connexins (e.g., phosphorylation) and is sensitive to environmental changes such as intracellular pH and Ca^{2+} concentration, membrane potential, and difference in the intercellular potential between adjacent interconnected cells (“voltage gating”). The N-termini of connexins appear to be especially important in the gating mechanism. One example of the physiological regulation of gap junctions occurs during mammalian childbirth. The muscle cells in the mammalian uterus must contract strongly and synchronously during labor to expel the fetus. To facilitate this coordinate activity, immediately prior to and during labor there is an approximately five- to tenfold increase in the amount of the major myometrial connexin, Cx43, and an increase in the number and size of gap junctions, which decrease rapidly postpartum.

Assembly of connexins, their trafficking within cells, and formation of functional gap junctions apparently depend on N-cadherin and its associated adapter proteins (e.g., α - and β -catenins, ZO-1, and ZO-2) as well as desmosomal proteins (plakoglobin, desmoplakin, and plakophilin-2). PDZ domains in ZO-1 and ZO-2 bind to the C-terminus of Cx43 and mediate its interaction with catenins and N-cadherin. The relevance of these relationships is particularly evident in the heart, which depends on gap junctions for rapid coordinated electrical coupling and on adjacent adherens junctions and desmosomes for mechanical coupling between cardiomyocytes to achieve the intercellular integration of electrical activity and movement required for normal cardiac function. It is noteworthy that ZO-1 serves as an adapter for adherens (see Figure 20-13), tight, and gap junctions, suggesting this and other adapters can help integrate the formation and functions of these diverse junctions.

 Mutations in connexin genes cause at least eight human diseases, including neurosensory deafness (Cx26 and Cx31), cataract or heart malformations (Cx43, Cx46, and Cx50), and the X-linked form of Charcot-Marie-Tooth disease (Cx32), which is marked by progressive degeneration of peripheral nerves. ■

KEY CONCEPTS of Section 20.2

Cell-Cell and Cell-ECM Junctions and Their Adhesion Molecules

- Polarized epithelial cells have distinct apical, basal, and lateral surfaces. Microvilli projecting from the apical surfaces of many epithelial cells considerably expand the cells' surface areas.

- Three major classes of cell junctions—anchoring junctions, tight junctions, and gap junctions—assemble epithelial cells into sheets and mediate communication between them (see Figures 20-1 and 20-10). Anchoring junctions can be further subdivided into adherens junctions, desmosomes, and hemidesmosomes.

- Adherens junctions and desmosomes are cadherin-containing anchoring junctions that bind the membranes of adjacent cells, giving strength and rigidity to the entire tissue.

- Cadherins are cell-adhesion molecules (CAMs) responsible for Ca^{2+} -dependent interactions between cells in epithelial and other tissues. They promote strong cell-cell adhesion by mediating both lateral intracellular and intercellular interactions.

- Adapter proteins that bind to the cytosolic domain of cadherins and other CAMs and adhesion receptors mediate the association of cytoskeletal and signaling molecules with the plasma membrane (see Figures 20-8 and 20-13). Strong cell-cell adhesion depends on the linkage of the interacting CAMs to the cytoskeleton.

- Hemidesmosomes are integrin-containing anchoring junctions that attach cells to elements of the underlying extracellular matrix.

- Integrins are a large family of $\alpha\beta$ heterodimeric cell-surface proteins that mediate both cell-cell and cell-matrix adhesions and inside-out and outside-in signaling in numerous tissues.

- Tight junctions block the diffusion of proteins and some lipids in the plane of the plasma membrane, contributing to the polarity of epithelial cells. They also limit and regulate the extracellular (paracellular) flow of water and solutes from one side of the epithelium to the other (see Figure 20-19). The two principal integral membrane proteins found in tight junctions are *occludin* and *claudin*.

- Gap junctions are constructed of multiple copies of connexin proteins, assembled into a transmembrane channel that interconnects the cytoplasms of two adjacent cells (see Figure 20-20). Small molecules and ions can pass through gap junctions, permitting metabolic and electrical coupling of adjacent cells.

20.3 The Extracellular Matrix I: The Basal Lamina

In animals, the extracellular matrix (ECM) helps organize cells into tissues and coordinates their cellular functions by activating intracellular signaling pathways that control cell growth, proliferation, and gene expression. ECM can directly influence cellular and tissue structure and function. In addition, ECM can serve as a repository for inactive or inaccessible signaling molecules (e.g., growth factors) that are released

to function when the ECM is disassembled or remodeled by hydrolyases, such as proteases. Indeed, hydrolyzed fragments of ECM macromolecules can themselves have independent biological activity. Many functions of the matrix require transmembrane adhesion receptors, including the integrins that bind directly to ECM components and that also interact, through adapter proteins, with the cytoskeleton.

Adhesion receptors bind to three types of molecules abundant in the extracellular matrix of all tissues (see Table 20-1):

- **Proteoglycans**, a group of glycoproteins that cushion cells and bind a wide variety of extracellular molecules;
- **Collagen fibers**, which provide structural integrity, mechanical strength, and resilience;
- **Soluble multi-adhesive matrix proteins**, such as laminin and fibronectin, which bind to and cross-link cell-surface adhesion receptors and other ECM components.

We begin our description of the structures and functions of these major ECM components in the context of the basal lamina—the specialized extracellular matrix sheet that plays a particularly important role in determining the overall architecture and function of epithelial tissue. In the next section, we discuss the ECM molecules commonly found in nonepithelial tissues, including connective tissue.

The Basal Lamina Provides a Foundation for Assembly of Cells into Tissues

In animals, most organized groups of cells in epithelial and non-epithelial tissues are underlain or surrounded by the basal lamina, a sheet-like meshwork of ECM components usually no more than 60–120 nm thick (Figure 20-21). The basal lamina is structured differently in different tissues. In columnar and other epithelia such as intestinal lining and skin, it is a foundation on which only one surface of the cells rests. In other tissues, such as muscle or fat, the basal lamina surrounds each cell. Basal laminae play important roles in regeneration after tissue damage and in embryonic development. For instance, the basal lamina helps four- and eight-celled embryos adhere together in a ball. In the development of the nervous system, neurons migrate along ECM pathways that contain basal lamina components. In higher animals, two distinct basal laminae are employed to form a tight barrier that limits diffusion of molecules between the blood and the brain (blood-brain barrier), and in the kidney a specialized basal lamina serves as a selective permeability blood filter. In muscle, the basal lamina helps protect the cell membranes from damage during contraction/relaxation and prevents muscular dystrophies. Thus the basal lamina is important for organizing cells into tissues and distinct compartments, tissue repair, forming permeability barriers, and

FIGURE 20-21 The basal lamina separating epithelial cells and some other cells from connective tissue. (a) Transmission electron micrograph of a thin section of cells (top) and underlying connective tissue (bottom). The electron-dense layer of the basal lamina can be seen to follow the undulation of the basal surface of the cells. (b) Electron micrograph of a quick-freeze deep-etch preparation of skeletal muscle showing the relation of the plasma membrane, basal lamina,

and surrounding connective tissue. In this preparation, the basal lamina is revealed as a meshwork of filamentous proteins that associates with the plasma membrane and the thicker collagen fibers of the connective tissue. FIGURE 20-22 Major protein components of the basal lamina. Type IV collagen and laminin each form two-dimensional networks,

which are cross-linked by entactin and perlecan molecules. [Adapted from B. Alberts et al., 1994, *Molecular Biology of the Cell*, 3d ed., Garland, p. 991.]

guiding migrating cells during development. It is therefore not surprising that basal lamina components have been highly conserved throughout evolution.

Most of the ECM components in the basal lamina are synthesized by the cells that rest on it. Four ubiquitous protein components are found in basal laminae (Figure 20-22):

- *Type IV collagen*, trimeric molecules with both rodlike and globular domains that form a two-dimensional network;
- *Laminins*, a family of multi-adhesive, cross-shaped proteins that form a fibrous two-dimensional network with type IV collagen and that also bind to integrins and other adhesion receptors;
- *Perlecan*, a large multidomain proteoglycan that binds to and cross-links many ECM components and cell-surface molecules;
- *Nidogen* (also called *entactin*), a rodlike molecule that cross-links type IV collagen, perlecan, and laminin and helps incorporate other components into the ECM and also stabilize basal laminae.

Other ECM molecules, such as members of the evolutionarily ancient family of glycoproteins called fibulins, are incorporated into various basal laminae, depending on the tissue and particular functional requirements of the basal lamina.

As depicted in Figure 20-1, one side of the basal lamina is linked to cells by adhesion receptors, including integrins in hemidesmosomes, which bind to laminin in the basal lamina. The other side of the basal lamina is anchored to the adjacent connective tissue by a layer of collagen fibers embedded in a proteoglycan-rich matrix. In stratified squamous epithelia (e.g., skin), this linkage is mediated by anchoring fibrils of type VII collagen. Together, the basal lamina and collagen-anchoring fibrils form the structure called the *basement membrane*.

Laminin, a Multi-adhesive Matrix Protein, Helps Cross-link Components of the Basal Lamina

Laminin, the principal multi-adhesive matrix protein in basal laminae, is a heterotrimeric protein comprising α , β , and γ chains. At least 16 laminin isoforms in vertebrates are assembled from five α , three β , and three γ chains and numbered to reflect the chain composition: laminin- $\alpha\beta\gamma$ (e.g., laminin-111 or laminin-511). Each laminin exhibits a distinctive pattern of tissue- and developmental-stage-specific expression. As shown in Figure 20-23 many laminins are large, cross-shaped proteins (molecular weight of about 820,000), although some are Y or rod shaped. Globular domains at the N-terminus of each subunit bind to one another and thus mediate the self-assembly of laminins into meshlike networks that, together with their binding to laminin receptors on cells, is essential for the assembly of basal laminae. Five globular *LG domains* at the C-terminus of the laminin α subunit mediate Ca^{2+} -dependent binding to cell-surface laminin receptors, including certain integrins (see Table 20-3) as well as sulfated glycolipids, syndecan, and dystroglycan, which will be described further in Section 20.4. Some of these interactions are via negatively charged carbohydrates on the receptors. LG domains are found in a wide variety of other proteins and can mediate binding to steroids and proteins as well as carbohydrates. Laminin is the principal basal laminal ligand of integrins.

Sheet-Forming Type IV Collagen Is a Major Structural Component of the Basal Lamina

Type IV collagen is, together with laminin, a principal structural component of all basal laminae and can bind to adhesion receptors, including some integrins. Collagen IV is one of at least 28 types of collagen in humans that participate in

FIGURE 20-23 Laminin, a heterotrimeric multi-adhesive matrix protein found in all basal laminae. (a) Schematic model of

cross-shaped laminin showing the general shape, location of globular domains, and coiled-coil region in which laminin's three chains are covalently linked by several disulfide bonds. Different regions of laminin bind to cell-surface receptors and various matrix components (indicated by arrows). Inset: laminins assemble into a lattice via

interactions between their N-terminal globular domains. (b) Electron micrographs of intact laminin molecule, showing its characteristic cross appearance (left) and the carbohydrate-binding LG domains near the C-terminus (right). [Part (a) adapted from G. R. Martin and R. Timpl, 1987, *Ann. Rev. Cell Biol.* **3**:57; Durbecq M. Laminins, 2010, *Cell Tissue Res.*

the formation of distinct extracellular matrices in various tissues (Table 20-4). There are also at least 20 additional collagen-like proteins (such as host defense collagens) in the human proteome. Although collagens differ in certain structural features and tissue distribution, all collagens are trimeric proteins made from three polypeptides, each encoded by one of at least 43 genes in humans, usually called collagen α chains. All three α chains can be identical (homotrimeric)

or different (heterotrimeric). All or parts of the three-stranded collagen molecule can twist together into a special triple helix called a *collagenous* triple helix. When there is more than one triple helical segment, these segments are joined by nonhelical regions of the protein. Within a helical segment, each of the three α chains twists into a left-handed helix, and the three chains then wrap around each other to form a right-handed triple helix (Figure 20-24).

FIGURE 20-24 The collagen triple helix. (a) (Left) Side view of the crystal structure of a polypeptide fragment whose sequence is based on repeating sets of three amino acids, Gly-X-Y, characteristic of collagen α chains. (Center) Each chain is twisted into a left-handed helix, and three chains wrap around each other to form a right-handed triple helix. The schematic model (right) clearly illustrates the triple helical nature of the structure and shows the left-handed twist of the individual collagen α chains (red line). (b) View down the axis of the triple helix. The proton side chains of the glycine residues (orange) point into the very narrow space between the polypeptide chains in the center of the triple helix. In collagen mutations in which other amino acids replace glycine, the proton in glycine is replaced by larger groups that disrupt the packing of the chains and destabilize the triple-helical structure. TABLE 20-4 Selected Collagens

Type	Molecule Composition	Structural Features	Representative Tissues
Fibrillar Collagens			
I	$[\alpha 1(I)]_2[\alpha 2(I)]$	300-nm-long fibrils	Skin, tendon, bone, ligaments, dentin, interstitial tissues
II	$[\alpha 1(II)]_3$	300-nm-long fibrils	Cartilage, vitreous humor
III	$[\alpha 1(III)]_3$	300-nm-long fibrils; often with type I	Skin, muscle, blood vessels
V	$[\alpha 1(V)]_2[\alpha 2(V)], [\alpha 1(V)]_3$	390-nm-long fibrils with globular N-terminal extension; often with type I	Cornea, teeth, bone, placenta, skin, smooth muscle
Fibril-Associated Collagens			
VI	$[\alpha 1(VI)][\alpha 2(VI)][\alpha 3(VI)]$	Lateral association with type I; periodic globular domains	Most interstitial tissues
IX	$[\alpha 1(IX)][\alpha 2(IX)][\alpha 3(IX)]$	Lateral association with type II; N-terminal globular domain; bound GAG	Cartilage, vitreous humor
Sheet-Forming and Anchoring Collagens			
IV	$[\alpha 1(IV)]_2[\alpha 2(IV)]$	Two-dimensional network	All basal laminae
VII	$[\alpha 1(VII)]_3$	Long fibrils	Below basal lamina of the skin
XV	$[\alpha 1(XV)]_3$	Core protein of chondroitin sulfate proteoglycan	Widespread; near basal lamina in muscle
Transmembrane Collagens			
XIII	$[\alpha 1(XIII)]_3$	Integral membrane protein	Hemidesmosomes in skin
XVII	$[\alpha 1(XVII)]_3$	Integral membrane protein	Hemidesmosomes in skin
Host Defense Collagens			
Collectins		Oligomers of triple helix; lectin domains	Blood, alveolar space
C1q		Oligomers of triple helix	Blood (complement)
Class A scavenger receptors		Homotrimeric membrane proteins	Macrophages

SOURCES: K. Kuhn, 1987, in R. Mayne and R. Burgeson, eds., *Structure and Function of Collagen Types*, Academic Press, p. 2, and M. van der Rest and R. Garrone, 1991, *FASEB J.* 5:2814.

The collagen triple helix can form because of an unusual abundance of three amino acids: glycine, proline, and a modified form of proline called hydroxyproline (see Figure 2-15). They make up the characteristic repeating sequence motif Gly-X-Y, where X and Y can be any amino acid but are often proline and hydroxyproline and less often lysine and hydroxylysine. Glycine is essential because its small side chain, a hydrogen atom, is the only one that can fit into the crowded center of the three-stranded helix (see Figure 20-24). Hydrogen bonds help hold the three chains together. Although the rigid peptidyl-proline and peptidyl-hydroxyproline linkages are not compatible with formation of a classic single-stranded α helix, they stabilize the distinctive three-stranded collagen

helix. The hydroxyl group in hydroxyproline helps hold its ring in a conformation that stabilizes the three-stranded helix.

There are several distinct cell-surface receptors for collagen IV and other types of collagen, discussed in the next section. These cell-surface receptors include certain integrins, discoidin domain receptors 1 and 2 (tyrosine kinase receptors), glycoprotein VI (on platelets), leukocyte-associated Ig-like receptor-1, members of the mannose receptor family, and a modified form of the protein CD44. They can play critical roles in helping to assemble ECM and in integrating cellular activity with the ECM.

The unique properties of each type of collagen are due mainly to differences in (1) the number and lengths of the

FIGURE 20-25 Structure and assembly of type IV collagen.

(a) Schematic representation of type IV collagen. This 400-nm-long molecule has a small noncollagenous globular domain at the N-terminus and a large globular domain at the C-terminus. The triple helix is interrupted by nonhelical segments that introduce flexible kinks in the molecule. Lateral interactions between triple helical segments, as well as head-to-head and tail-to-tail interactions between the globular domains, form dimers, tetramers, and higher-order complexes, yielding a sheet-like network. Multiple, unusual sulfilimine ($-S=N-$) or thioether bonds between hydroxylysine (or lysine) and methionine residues covalently cross-link some adjacent C-terminal domains and contribute to the stability of the network. (b) Electron micrograph of type IV collagen network formed in vitro. The lacy appearance results from the flexibility of the molecule, the side-to-side binding between triple-helical segments (white arrows), and the interactions between C-terminal globular domains (yellow arrows). [Part (a) adapted from A. Boutaud, 2000, *J. Biol. Chem.* **275**:30716. Part (b) courtesy of P. Yurchenco; see P. Yurchenco and G. C. Ruben, 1987, *J. Cell Biol.* **105**:2559.]

collagenous, triple-helical segments; (2) the segments that flank or interrupt the triple-helical segments and that fold into other kinds of three-dimensional structures; and (3) the covalent modification of the α chains (e.g., hydroxylation, glycosylation, oxidation, cross-linking). For example, the chains in type IV collagen are designated IV α chains. Mammals express six homologous IV α chains, which assemble into three different heterotrimeric type IV collagens with distinct properties. All subtypes of type IV collagen, however, form a 400-nm-long triple helix (Figure 20-25) that is interrupted about 24 times with nonhelical segments and flanked by large globular domains at the C-termini of the chains and smaller globular domains at the N-termini. The nonhelical regions introduce flexibility into the molecule. Through both lateral associations and interactions entailing the globular N- and C-termini, type IV collagen molecules assemble into a branching, irregular two-dimensional fibrous network that forms a lattice on which, together with the laminin lattice, the basal lamina is built (see Figures 20-22 and 20-25).

In the kidney, a double basal lamina called the glomerular basement membrane separates the epithelium that lines the urinary space from the endothelium that lines the surrounding blood-filled capillaries. Defects in this structure, which is responsible for ultrafiltration of the blood and initial urine formation, can lead to renal failure. For instance, mutations that alter the C-terminal globular domain of certain IV α chains are associated with progressive renal failure as well as sensorineural hearing loss and ocular abnormalities, a condition known as *Alport's syndrome*. In *Goodpasture's syndrome*, a relatively rare autoimmune disease, antibodies bind to the $\alpha 3$ chains of type IV collagen found in the glomerular basement membrane and lungs. This binding sets off an im-

mune response that causes cellular damage resulting in progressive renal failure and pulmonary hemorrhage. ■

Perlecan, a Proteoglycan, Cross-links Components of the Basal Lamina and Cell-Surface Receptors

Perlecan, the major secreted proteoglycan in basal laminae, consists of a large multidomain core protein (~470 kDa) made up of repeats of five distinct domains, including laminin-like LG domains and Ig domains. The many globular repeats give

it the appearance of a string of pearls when visualized by electron microscopy; hence the name perlecan. Perlecan is a glycoprotein that contains three types of covalent polysaccharide chains: N-linked (see Chapter 14), O-linked, and glycosaminoglycans (GAGs) (O-linked sugars and GAGs are discussed further in Section 20.4). GAGs are long polymers of repeating disaccharides. Glycoproteins containing covalently attached GAG chains are called **proteoglycans**. The protein constituent of a proteoglycan is usually called the *core* protein, onto which the GAG chains are attached. Both the protein and the GAG components of perlecan contribute to its ability to incorporate into and define the structure and function of basal laminae. Because of its multiple domains and polysaccharide chains that have distinctive binding properties, perlecan binds to dozens of other molecules, including other ECM components (e.g., laminin, nidogen), cell-surface receptors, and polypeptide growth factors. Simultaneous binding to these molecules results in perlecan-mediated cross-linking. Perlecan can be found in basal laminae and non-basal-laminae ECM. The adhesion receptor dystroglycan can bind perlecan directly, via its LG domains, and indirectly, via its binding to laminin. In humans, mutations in the perlecan gene can lead either to dwarfism or to muscle abnormalities, apparently due to dysfunction of the neuromuscular junction that controls muscle firing.

KEY CONCEPTS of Section 20.3

The Extracellular Matrix I: The Basal Lamina

- The basal lamina, a thin meshwork of extracellular matrix (ECM) molecules, separates most epithelia and other organized groups of cells from adjacent connective tissue. Together, the basal lamina and the immediately adjacent collagen network form a structure called the basement membrane.
- Four ECM proteins are found in all basal laminae (see Figure 20-22): laminin (a multi-adhesive matrix protein), type IV collagen, perlecan (a proteoglycan), and nidogen/enactin.
- Cell-surface adhesion receptors such as integrin anchor cells to the basal lamina, which in turn is connected to other ECM components (see Figure 20-1). Laminin in the basal lamina is the principal ligand of $\alpha 6 \beta 4$ integrin (see Table 20-3).
- Laminin and other multi-adhesive matrix proteins are multidomain molecules that bind multiple adhesion receptors and ECM components.
- The large, flexible molecules of type IV collagen interact end to end and laterally to form a meshlike scaffold to which other ECM components and adhesion receptors can bind (see Figures 20-22 and 20-25).
- Type IV collagen is a member of the collagen family of proteins distinguished by the presence of repeating tripeptide sequences of Gly-X-Y that give rise to the collagen triple-helical structure (see Figure 20-24). Different collagens are distinguished by the length and chemical modifications of

their α chains and by the presence of segments that interrupt or flank their triple-helical regions.

- Perlecan, a large secreted proteoglycan present primarily in the basal lamina, binds many ECM components and adhesion receptors. Proteoglycans consist of membrane-associated or secreted core proteins covalently linked to one or more specialized polysaccharide chains called glycosaminoglycans (GAGs).

20.4 The Extracellular Matrix II: Connective Tissue

Connective tissue such as tendon and cartilage differs from other solid tissues in that most of its volume is made up of extracellular matrix rather than cells. This matrix is packed with insoluble protein fibers. Key ECM components in connective tissue, some of which are found in other types of tissues as well, are:

- *Collagens*, trimeric molecules that are often bundled together into fibers (*fibrillar collagens*);
- *Glycosaminoglycans (GAGs)*, specialized linear polysaccharide chains of specific repeating disaccharides that can be highly hydrated and confer diverse binding and physical properties (e.g., resistance to compression);
- *Proteoglycans*, glycoproteins containing one or more covalently bound GAG chains
- *Multi-adhesive proteins*, large multidomain proteins often comprising many copies ("repeats") of a few distinctive domains that bind to and cross-link a variety of adhesive receptors and ECM components;
- *Elastin*, a protein that forms the amorphous core of elastic fibers.

Collagen is the most abundant fibrous protein in connective tissue. Rubber-like elastin fibers, which can be stretched and relaxed, are also present in deformable sites (e.g., skin, tendons, heart). The fibronectins, a family of multi-adhesive matrix proteins, form their own distinct fibrils in the matrix of most connective tissues. Although several types of cells are found in connective tissues, the various ECM components are produced largely by cells called **fibroblasts**. In this section we explore the structure and function of the various components in the ECM of connective tissue, as well as how the ECM is degraded and remodeled by a variety of specialized proteases.

Fibrillar Collagens Are the Major Fibrous Proteins in the ECM of Connective Tissues

About 80–90 percent of the collagen in the body consists of *fibrillar collagens* (types I, II, and III), located primarily in connective tissues (see Table 20-4). Because of its abundance in tendon-rich tissue such as rat tail, type I collagen is easy to isolate and was the first collagen to be characterized. Its

FIGURE 20-26 Biosynthesis of fibrillar collagens.

Step 1: Procollagen α chains are synthesized on ribosomes associated with the endoplasmic reticulum (rough ER), and in the ER asparagine-linked oligosaccharides are added to the C-terminal propeptide.

Step 2: Propeptides associate to form trimers and are covalently linked by disulfide bonds, and selected residues in the Gly-X-Y triplet repeats are covalently modified (certain prolines and lysines are hydroxylated, galactose or galactose-glucose [hexagons] are attached to some hydroxylysines, prolines are *cis* $\rightarrow$ *trans* isomerized).

Step 3: The modifications facilitate zipperlike formation, stabilization of triple helices, and binding by the chaperone protein Hsp47 (see Chapter 13), which may stabilize the helices or prevent premature aggregation of the trimers or both.

Steps 4 and 5: The folded procollagens are transported to and through the Golgi apparatus, where some lateral association into small bundles takes place. The chains are then secreted (step 6), the N- and C-terminal propeptides are removed (step 7), and the trimers assemble into fibrils and are covalently cross-linked (step 8). The 67-nm staggering of the trimers gives the fibrils a striated appearance in electron micrographs (inset). [Adapted from A. V. Persikov and B. Brodsky, 2002, *Proc. Nat'l. Acad. Sci. USA* 99:1101–1103.]

fundamental structural unit is a long (300-nm), thin (1.5-nm-diameter) triple helix (see Figure 20-24) consisting of two $\alpha 1(I)$ chains and one $\alpha 2(I)$ chain, each 1050 amino acids in length. The triple-stranded molecules pack tightly together and wrap around each other forming *microfibrils* that associate into higher-order polymers called collagen *fibrils*, which in turn often aggregate into larger bundles called collagen *fibers* (Figure 20-26).

Classes of collagen that are less abundant, but nevertheless important, include *fibril-associated collagens*, which link the fibrillar collagens to one another or to other ECM components; *sheet-forming and anchoring collagens*, which form two-dimensional networks in basal laminae (type IV) and connect the basal lamina in skin to the underlying connective tissue (type VII); *transmembrane collagens*, which function as adhesion receptors; and *host defense collagens*, which help the body recognize and eliminate pathogens. Interestingly, several collagens (e.g., types IX, XVIII, and XV) are also proteoglycans with covalently attached GAGs (see Table 20-4).

Fibrillar Collagen Is Secreted and Assembled into Fibrils Outside the Cell

Fibrillar collagens are secreted proteins, produced primarily by fibroblasts in the ECM. Collagen biosynthesis and secretion follow the normal pathway for a secreted protein, described in

detail in Chapters 13 and 14. The collagen α chains are synthesized as longer precursors, called pro- α chains, by ribosomes attached to the endoplasmic reticulum (ER). The pro- α chains undergo a series of covalent modifications and fold into triple-helical *procollagen* molecules before their release from cells (see Figure 20-26).

After the secretion of procollagen from the cell, extracellular peptidases remove the N-terminal and C-terminal propeptides. In fibrillar collagens, the resulting molecules, which consist almost entirely of a triple-stranded helix, associate laterally to generate fibrils with a diameter of 50–200 nm. In fibrils, adjacent collagen molecules are displaced from one another by 67 nm, about one-quarter of their length. This staggered array produces a striated effect that can be seen in both light and electron microscopic images of collagen fibrils (see Figure 20-26, *inset*). The unique properties of the fibrillar collagens are mainly due to the formation of fibrils.

Short non-triple-helical segments at either end of the fibrillar collagen α chains are of particular importance in the formation of collagen fibrils. Lysine and hydroxylysine side chains in these segments are covalently modified by extracellular lysyl oxidases to form aldehydes in place of the amine group at the end of the side chain. These reactive aldehyde groups form covalent cross-links with lysine, hydroxylysine, and histidine residues in adjacent molecules. The cross-links stabilize the side-by-side packing of collagen molecules and generate a very

FIGURE 20-27 Interactions of fibrous collagens with nonfibrous fibril-associated collagens. (a) In tendons, type I fibrils are all oriented in the direction of the stress applied to the tendon. Proteoglycans and type VI collagen bind noncovalently to fibrils, coating the surface. The microfibrils of type VI collagen, which contain globular and triple-helical segments, bind to type I fibrils and link them together into thicker fibers. (b) In cartilage, type IX collagen molecules are covalently bound at regular intervals along type II fibrils. A chondroitin sulfate chain, covalently linked to the $\alpha 2(\text{IX})$ chain at the flexible kink, projects outward from the fibril, as does the globular N-terminal region.

[Part (a), see R. R. Bruns et al., 1986, *J. Cell Biol.* **103**:393. Part (b), see L. M. Shaw and B. Olson, 1991, *Trends Biochem. Sci.* **18**:191.]

strong fibril. The removal of the propeptides and covalent cross-linking take place in the extracellular space to prevent the potentially catastrophic assembly of fibrils within the cell.

 The post-translational modifications of pro- α chains are crucial for the formation of mature collagen molecules and their assembly into fibrils. Defects in these modifications have serious consequences, as ancient mariners frequently experienced. For example, ascorbic acid (vitamin C) is an essential cofactor for the hydroxylases responsible for adding hydroxyl groups to proline and lysine residues in pro- α chains. In cells deprived of ascorbate, as in the disease *scurvy*, the pro- α chains are not hydroxylated sufficiently to form stable triple-helical procollagen at normal body temperature, and the procollagen that forms cannot assemble into normal fibrils. Without the structural support of collagen, blood vessels, tendons, and skin become fragile. Fresh fruit in the diet can supply sufficient vitamin C to support the formation of normal collagen. Historically, British sailors were provided with limes to prevent scurvy, leading to their being called “limeys.” Mutations in lysyl hydroxylase genes also can cause connective-tissue defects. ■

Type I and II Collagens Associate with Nonfibrillar Collagens to Form Diverse Structures

Collagens differ in the structures of the fibers they form and how these fibers are organized into networks. Of the predominant types of collagen found in connective tissues, type I collagen forms long fibers, whereas networks of type II collagen are more meshlike. In tendons, for instance, the long type I collagen fibers connect muscles to bones and must withstand enormous forces. Because type I collagen fibers have great tensile strength, tendons usually can be stretched without being broken. Indeed, gram for gram, type I collagen is stronger than steel. Two quantitatively minor fibrillar collagens, type V and type XI, co-assemble into fibers with type I collagen, thereby regulating the structures and properties of the fibers. Incorporation of type V collagen, for example, results in smaller-diameter fibers.

Type I collagen fibrils are also used as the reinforcing rods in the construction of bone. Bones and teeth are hard and strong because they contain large amounts of *dahlite*, a crystalline calcium- and phosphate-containing mineral. Most bones are about 70 percent mineral and 30 percent protein, the vast majority of which is type I collagen. Bones form when certain cells (chondrocytes and osteoblasts) secrete collagen fibrils that are then mineralized by deposition of small *dahlite* crystals.

In many connective tissues, particularly skeletal muscle, proteoglycans and a fibril-associated collagen called type VI collagen are noncovalently bound to the sides of type I fibrils and may bind the fibrils together to form thicker collagen fibers (Figure 20-27a). Type VI collagen is unusual in that the molecule consists of a relatively short triple helix with globular domains at both ends. The lateral association of two type VI monomers generates an “antiparallel” dimer. The end-to-end association of these dimers through their globular domains forms type VI “microfibrils.” These microfibrils have a beads-on-a-string appearance, with about 60-nm-long triple-helical regions separated by 40-nm-long globular domains.

The fibrils of type II collagen, the major collagen in cartilage, are smaller in diameter than type I fibrils and are oriented randomly in a viscous proteoglycan matrix. The rigid collagen fibrils impart strength to the matrix and allow it to resist large deformations in shape. Type II fibrils are cross-linked to matrix proteoglycans by type IX collagen, another fibril-associated collagen. Type IX collagen and several related types have two or three triple-helical segments connected by flexible kinks and an N-terminal globular segment (Figure 20-27b). The globular N-terminal segment of type IX collagen extends from the fibrils at the end of one of its helical segments, as does a GAG chain that is sometimes

linked to one of the type IX chains. These protruding nonhelical structures are thought to anchor the type II fibril to proteoglycans and other components of the matrix. The interrupted triple-helical structure of type IX and related collagens prevents them from assembling into fibrils, although they can associate with fibrils formed from other collagen types and form covalent cross-links to them.

Mutations affecting type I collagen and its associated proteins cause a variety of human diseases. Certain mutations in the genes encoding the type I collagen $\alpha 1(I)$ or $\alpha 2(I)$ chains lead to *osteogenesis imperfecta*, or brittle-bone disease. Because every third position in a collagen α chain must be a glycine for the triple helix to form (see Figure 20-24), mutations of glycine to almost any other amino acid are deleterious, resulting in poorly formed and unstable helices. Only one defective α chain of the three in a collagen molecule can disrupt the whole molecule's triple-helical structure and function. A mutation in a single copy (allele) of either the $\alpha 1(I)$ gene or the $\alpha 2(I)$ gene, which are located on nonsex chromosomes (autosomes), can cause this disorder. Thus it normally shows autosomal dominant inheritance (see Chapter 5).

Absence or malfunctioning of collagen-fibril-associated microfibrils in muscle tissue due to mutations in the type VI collagen genes cause dominant or recessive congenital muscular dystrophies with generalized muscle weakness, respiratory insufficiency, muscle wasting, and muscle-related joint abnormalities. Skin abnormalities have also been reported with type VI collagen disease. ■

Proteoglycans and Their Constituent GAGs Play Diverse Roles in the ECM

As we saw with perlecan in the basal lamina, proteoglycans play an important role in cell-ECM adhesion. Proteoglycans are a subset of secreted or cell-surface-attached glycoproteins containing covalently linked specialized polysaccharide chains called **glycosaminoglycans (GAGs)**. GAGs are long linear polymers of specific repeating disaccharides. Usually one sugar is either a uronic acid (D-glucuronic acid or L-iduronic acid) or D-galactose; the other sugar is N-acetylglucosamine or N-acetylgalactosamine (Figure 20-28). One or both of the sugars contain at least one anionic group (carboxylate or sulfate). Thus each GAG chain bears many negative charges. GAGs are classified into several major types based on the nature of the repeating disaccharide unit: heparan sulfate, chondroitin sulfate, dermatan sulfate, keratan sulfate, and hyaluronan. A hypersulfated form of heparan sulfate called *heparin*, produced mostly by mast cells, plays a key role in allergic reactions. It is also used medically as an anticlotting drug because of its ability to activate a natural clotting inhibitor called antithrombin III.

With the exception of hyaluronan, which is discussed below, all the major GAGs occur naturally as components of proteoglycans. Like other secreted and transmembrane glycoproteins, proteoglycan core proteins are synthesized in the endoplasmic reticulum, and the GAG chains are assembled on and covalently attached to these cores in the Golgi complex.

(a) Hyaluronan ($n \leq 25,000$)

(b) Chondroitin (or dermatan) sulfate ($n \leq 250$)

(c) Heparin/Heparan sulfate ($n = 200$)

(d) Keratan sulfate ($n = 20-40$)

FIGURE 20-28 The repeating disaccharides of glycosaminoglycans (GAGs), the polysaccharide components of proteoglycans. Each of the four classes of GAGs is formed by polymerization of monomer units into repeats of a particular disaccharide and subsequent modifications, including addition of sulfate groups and inversion (epimerization) of the carboxyl group on carbon 5 of D-glucuronic acid to yield L-iduronic acid. The squiggly lines represent covalent bonds that are oriented either above (D-glucuronic acid) or below (L-iduronic acid) the ring. Heparin is generated by hypersulfation of heparan sulfate, whereas hyaluronan is unsulfated.

FIGURE 20-29 Hydroxyl (O-) linked polysaccharides. (a) Synthesis of a glycosaminoglycan (GAG), in this case chondroitin sulfate, is initiated by transfer of a xylose residue to a serine residue in the core protein, most likely in the Golgi complex, followed by sequential addition of two galactose residues. Glucuronic acid and N-acetylgalactosamine residues are then added sequentially to these linking sugars, forming the chondroitin sulfate chain. Heparan sulfate chains are connected to core proteins by the same three-sugar linker. (b) Mucin-type O-linked chains are covalently bound to glycoproteins via an N-acetylgalactosamine (GalNAc) monosaccharide to which are covalently attached a variety of other sugars. (c) Certain specialized O-linked oligosaccharides, such as those found in the protein dystroglycan, are bound to proteins via mannose (Man) monosaccharides.

To generate heparan or chondroitin sulfate chains, a three-sugar “linker” is first attached to the hydroxyl side chains of certain serine residues in a core protein; thus the linker is called an *O*-linked oligosaccharide (Figure 20-29). In contrast, the linkers for the addition of keratan sulfate chains are oligosaccharide chains attached to asparagine residues; such *N*-linked oligosaccharides are present in many glycoproteins (see Chapter 14), although only a subset carry GAG chains. All GAG chains are elongated by the alternating addition of sugar monomers to form the disaccharide repeats characteristic of a particular GAG; the chains are often modified subsequently by the covalent linkage of small molecules such as sulfate. The mechanisms responsible for determining which proteins are modified with GAGs, the sequence of disaccharides to be added, the sites to be sulfated, and the lengths of the GAG chains are unknown. The ratio of poly-

saccharide to protein in all proteoglycans is much higher than that in most other glycoproteins.

Function of GAG Chain Modifications As is the case with the sequence of amino acids in proteins, the arrangement of the sugar residues in GAG chains and the modification of specific sugars in the chains can determine their function and that of the proteoglycans containing them. For example, groupings of certain modified sugars in the GAG chains of heparin sulfate proteoglycans can control the binding of growth factors to certain receptors or the activities of proteins in the blood-clotting cascade.

In the past, the chemical and structural complexity of proteoglycans posed a daunting barrier to analyzing and understanding their structures and many diverse functions. In recent years, investigators employing classical and state-of-the-art biochemical techniques, mass spectrometry, and genetics have begun to elucidate the detailed structures and functions of these ubiquitous ECM molecules. The results of ongoing studies suggest that sets of sugar-residue sequences containing common modifications, rather than single unique sequences, are responsible for specifying distinct GAG functions. A case in point is a set of five-residue (pentasaccharide) sequences found in a subset of heparin GAGs that controls the activity of antithrombin III (ATIII), an inhibitor of the key blood-clotting protease thrombin. When these pentasaccharide sequences in heparin are sulfated at two specific positions (Figure 20-30), heparin can activate ATIII, thereby inhibiting clot formation. Several other sulfates can be present in the active pentasaccharide in various combinations, but they are not essential for the anticoagulating activity of heparin. The rationale for generating sets of similar active sequences rather than a single unique sequence is not well understood.

Diversity of Proteoglycans The proteoglycans constitute a remarkably diverse group of molecules that are abundant in the extracellular matrix of all animal tissues and are also

FIGURE 20-30 Pentasaccharide GAG sequence that regulates the activity of antithrombin III (ATIII). Sets of modified five-residue sequences in the much longer GAG called heparin with the composition shown here bind to ATIII and activate it, thereby inhibiting blood clotting. The sulfate groups in red type are essential for this heparin function; the modifications in blue type may be present but are not essential. Other sets of modified GAG sequences are thought to regulate the activity of other target proteins.

expressed on the cell surface. For example, of the five major classes of heparan sulfate proteoglycans, three are located in the extracellular matrix (perlecan, agrin, and type XVIII collagen) and two are cell-surface proteins. The latter include integral membrane proteins (syndecans) and GPI-anchored proteins (glypicans); the GAG chains in both types of cell-surface proteoglycans extend into the extracellular space. The sequences and lengths of proteoglycan core proteins vary considerably, and the number of attached GAG chains ranges from just a few to more than 100. Moreover, a core protein is often linked to two different types of GAG chains, generating a “hybrid” proteoglycan. The basal laminal proteoglycan perlecan is primarily a heparan sulfate proteoglycan (HSPG) with three to four GAG chains, although it sometimes can have a bound chondroitin sulfate chain. Additional diversity in proteoglycans occurs because the numbers of chains, compositions, and sequences of the GAGs attached to otherwise identical core proteins can differ considerably. Laboratory generation and analysis of mutants with defects in proteoglycan production in *Drosophila melanogaster* (fruit fly), *C. elegans* (roundworm), and mice have clearly shown that proteoglycans play critical roles in development, most likely as modulators of various signaling pathways.

Syndecans are cell-surface proteoglycans expressed by epithelial and nonepithelial cells that bind to collagens and multiadhesive matrix proteins such as fibronectin, anchoring cells to the extracellular matrix. Like that of many integral membrane proteins, the cytosolic domain of syndecan interacts with the actin cytoskeleton and in some cases with intracellular regulatory molecules. In addition, cell-surface proteoglycans such as syndecan bind many protein growth factors and other external signaling molecules, thereby helping to regulate cellular metabolism and function. For instance, syndecans in the hypothalamic region of the brain modulate feeding behavior in response to food deprivation. They do so by participating in the binding to cell-surface receptors of antisatiety peptides that help control feeding behavior. In the fed state, the syndecan extracellular domain decorated with heparan sulfate chains is released from the surface by proteolysis, thus suppressing the activity of the antisatiety peptides and feeding behavior. In mice engineered to overexpress the *syndecan-1* gene in the hypothalamic region of the brain and other tissues, normal control of feeding by antisatiety peptides is disrupted and the animals overeat and become obese.

Hyaluronan Resists Compression, Facilitates Cell Migration, and Gives Cartilage Its Gel-like Properties

Hyaluronan, also called hyaluronic acid (HA) or hyaluronate, is a nonsulfated GAG (see Figure 20-28a) made by a plasma-membrane-bound enzyme called HA synthase and is directly secreted into the extracellular space as it is synthesized. (A similar approach is used by plant cells to make their ECM component cellulose.) HA is a major component of the extracellular matrix that surrounds migrating and proliferating cells, particularly in embryonic tissues. In addition, hyaluronan

forms the backbone of complex proteoglycan aggregates found in many extracellular matrices, particularly cartilage. Because of its remarkable physical properties, hyaluronan imparts stiffness and resilience as well as a lubricating quality to many types of connective tissue such as joints.

Hyaluronan molecules range in length from a few disaccharide repeats to ~25,000. The typical hyaluronan in joints such as the elbow has 10,000 repeats for a total mass of 4×10^6 Da and length of 10 μm (about the diameter of a small cell). Individual segments of a hyaluronan molecule fold into a rodlike conformation because of the β glycosidic linkages between the sugars and extensive intrachain hydrogen bonding. Mutual repulsion between negatively charged carboxylate groups that protrude outward at regular intervals also contributes to these local rigid structures. Overall, however, hyaluronan is not a long, rigid rod as is fibrillar collagen; rather, in solution it is very flexible, bending and twisting into many conformations, forming a random coil.

Because of the large number of anionic residues on its surface, the typical hyaluronan molecule binds a large amount of water and behaves as if it were a large hydrated sphere with a diameter of ~500 nm. As the concentration of hyaluronan increases, the long chains begin to entangle, forming a viscous gel. Even at low concentrations, hyaluronan forms a hydrated gel; when placed in a confining space, such as in a matrix between two cells, the long hyaluronan molecules will tend to push outward. This outward pushing creates a swelling, or *turgor pressure*, within the extracellular space. In addition, the binding of cations by carboxylate (COO^-) groups on the surface of hyaluronan increases the concentration of ions and thus the osmotic pressure in the gel. As a result, large amounts of water are taken up into the matrix, contributing to the turgor pressure. These swelling forces give connective tissues their ability to resist compression forces, in contrast with collagen fibers, which are able to resist stretching forces.

Hyaluronan is bound to the surface of many migrating cells by a number of adhesion receptors, such as the receptor called CD44, containing HA-binding domains, each with a similar three-dimensional conformation. Because of its loose, hydrated, porous nature, the hyaluronan “coat” bound to cells appears to keep cells apart from one another, giving them the freedom to move about and proliferate. The cessation of cell movement and the initiation of cell-cell attachments are frequently correlated with a decrease in hyaluronan, a decrease in HA receptors, and an increase in the extracellular enzyme hyaluronidase, which degrades hyaluronan in the matrix. These alterations of hyaluronan are particularly important during the many cell migrations that facilitate differentiation and in the release of a mammalian egg cell (oocyte) from its surrounding cells after ovulation.

The predominant proteoglycan in cartilage, called *aggrecan*, assembles with hyaluronan into very large aggregates, illustrative of the complex structures that proteoglycans sometimes form. The backbone of the cartilage proteoglycan aggregate is a long molecule of hyaluronan to which multiple aggrecan molecules are bound tightly but noncovalently

FIGURE 20-31 Structure of proteoglycan aggregate from cartilage. (a) Electron micrograph of an aggrecan aggregate from fetal bovine epiphyseal cartilage. Aggrecan core proteins are bound at ~40-nm intervals to a molecule of hyaluronan. (b) Schematic representation of an aggrecan monomer bound to hyaluronan (yellow). In aggrecan, both keratan sulfate (green) and chondroitin sulfate (orange) chains are attached to the core protein. The N-terminal domain of the core protein binds noncovalently to a hyaluronan molecule. Binding is facilitated by a link protein, which binds to both the hyaluronan molecule and the aggrecan core protein. Each aggrecan core protein has 127 Ser-Gly sequences at which GAG chains can be added. The molecular weight of an aggrecan monomer averages 2×10^6 . The entire aggregate, which may contain upward of 100 aggrecan monomers, has a molecular weight in excess of 2×10^8 and is about as large as the bacterium *E. coli*. [Part (a) from J. A. Buckwalter and L. Rosenberg, 1983, *Coll. Rel. Res.* 3:489; courtesy of L. Rosenberg.]

(Figure 20-31). A single aggrecan aggregate, one of the largest macromolecular complexes known, can be more than 4 μm long and have a volume larger than that of a bacterial cell. These aggregates give cartilage its unique gel-like properties and its resistance to deformation, essential for distributing the load in weight-bearing joints.

The aggrecan core protein (~250,000 MW) has one N-terminal globular domain that binds with high affinity to a specific decasaccharide sequence within hyaluronan. This specific sequence is generated by covalent modification of some of the repeating disaccharides in the hyaluronan chain. The interaction between aggrecan and hyaluronan is facilitated by a link protein that binds to both the aggrecan core protein and hyaluronan (Figure 20-31b). Aggrecan and the link protein have in common a “link” domain, ~100 amino acids long, that is found in numerous matrix and cell-surface hyaluronan-binding proteins in both cartilaginous and noncartilaginous tissues. Almost certainly these proteins arose in the course of evolution from a single ancestral gene that encoded just this domain.

Fibronectins Interconnect Cells and Matrix, Influencing Cell Shape, Differentiation, and Movement

Many different cell types synthesize **fibronectin**, an abundant multi-adhesive matrix protein found in all vertebrates. The discovery that fibronectin functions as an adhesive molecule stemmed from observations that it is present on the surfaces of normal fibroblastic cells, which adhere tightly to petri dishes in laboratory experiments, but is absent from the surfaces of tumorigenic (i.e., cancerous) cells, which adhere weakly. The 20 or so isoforms of fibronectin are generated by alternative splicing of the RNA transcript produced from a single gene (see Figure 4-16). Fibronectins are essential for the migration and differentiation of many cell types in embryogenesis. These proteins are also important for wound healing because they promote blood clotting and facilitate the migration of macrophages and other immune cells into the affected area.

Fibronectins help attach cells to the extracellular matrix by binding to other ECM components, particularly fibrous collagens and heparan sulfate proteoglycans, and to cell-surface adhesion receptors such as integrins (see Figure 20-2). Through their interactions with adhesion receptors, fibronectins influence the shape and movement of cells and the organization of the cytoskeleton. Conversely, by regulating their receptor-mediated attachments to fibronectin and other ECM components, cells can sculpt the immediate ECM environment to suit their needs.

Fibronectins are dimers of two similar polypeptides linked at their C-termini by two disulfide bonds; each chain is about 60–70 nm long and 2–3 nm thick. Partial digestion of fibronectin with low amounts of proteases and analysis of the fragments showed that each chain comprises several functional regions with different ligand-binding specificities (Figure 20-32a). Each region, in turn, contains multiple copies of certain sequences that can be classified into one of three types. These classifications are designated fibronectin type I, II, and III repeats, on the basis of similarities in amino acid sequence, although the sequences of any two repeats of a given type are not identical. These linked repeats give the molecule the appearance of beads on a string. The combination of different repeats composing the regions confers on fibronectin its ability to bind multiple ligands.

FIGURE 20-32 Organization of fibronectin and its binding to integrin. (a) Scale model of fibronectin is shown docked by two type III repeats to the extracellular domains of integrin. Only one of the two similar chains, which are linked by disulfide bonds near their C-termini, in the dimeric fibronectin molecule is shown. Each chain contains about 2446 amino acids and is composed of three types of repeating amino acid sequences (type I, II, or III repeats) or domains. The EIIIA, EIIIB—both type III repeats—and IIICS domain are variably spliced into the structure at locations indicated by arrows. Circulating fibronectin lacks one or both of EIIIA and EIIIB. At least five different sequences may be present in the IIICS region as a result of alternative splicing

(see Figure 4-16). Each chain contains several multirepeat-containing regions, some of which contain specific binding sites for heparan sulfate, fibrin (a major constituent of blood clots), collagen, and cell-surface integrins. The integrin-binding domain is also known as the cell-binding domain. Structures of fibronectin's domains were determined from fragments of the molecule. (b) A high-resolution structure shows that the RGD binding sequence (red) extends outward in a loop from its compact type III domain on the same side of fibronectin as the synergy region (blue), which also contributes to high-affinity binding to integrins. [Adapted from D. J. Leahy et al., 1996, *Cell* 84:161.]

One of the type III repeats in the cell-binding region of fibronectin mediates binding to certain integrins. The results of studies with synthetic peptides corresponding to parts of this repeat identified the tripeptide sequence Arg-Gly-Asp, called the *RGD sequence*, as the minimal sequence within this repeat required for recognition by those integrins. In one study, heptapeptides containing the RGD sequence or a variation of this sequence were tested for their ability to mediate

the adhesion of rat kidney cells to a culture dish. The results showed that heptapeptides containing the RGD sequence mimicked intact fibronectin's ability to stimulate integrin-mediated adhesion, whereas variant heptapeptides lacking this sequence were ineffective (Figure 20-33).

A three-dimensional model of fibronectin binding to integrin based on partial structures of both fibronectin and integrin has been assembled. In a high-resolution structure of the

EXPERIMENTAL FIGURE 20-33 A specific tripeptide sequence (RGD) in the cell-binding region of fibronectin is required for adhesion of cells. The cell-binding region of fibronectin contains an integrin-binding hexapeptide sequence, GRGDSP in the single-letter amino acid code (see Figure 2-14). Together with an additional C-terminal cysteine (C) residue, this heptapeptide and several variants were synthesized chemically. Different concentrations of each synthetic peptide were added to polystyrene dishes that had the protein immunoglobulin G (IgG) firmly attached to their surfaces; the peptides were then chemically cross-linked to the IgG. Subsequently, cultured normal rat kidney cells were added to the dishes and incubated for 30 minutes to allow adhesion. After the nonbound cells were washed away, the relative amounts of cells that had adhered firmly were determined by staining the bound cells with a dye and measuring the intensity of the staining with a spectrophotometer. The results shown here indicate that cell adhesion increased above the background level with increasing peptide concentration for those peptides containing the RGD sequence but not for the variants lacking this sequence (modification underlined). [From M. D. Pierschbacher and E. Ruoslahti, 1984, *Proc. Nat'l. Acad. Sci. USA* 81:5985.]

EXPERIMENTAL FIGURE 20-34 Integrins mediate linkage between fibronectin in the extracellular matrix and the cytoskeleton. (a) Immunofluorescent micrograph of a fixed cultured fibroblast showing colocalization of the $\alpha 5 \beta 1$ integrin (green) and actin-containing stress fibers (red). The cell was incubated with two types of monoclonal antibody: an integrin-specific antibody linked to a green fluorescing dye and an actin-specific antibody linked to a red fluorescing dye. Stress fibers are long bundles of actin microfilaments that radiate inward from points where the cell contacts a substratum. At the distal end of these fibers, near the plasma membrane, the coincidence of actin (red) and fibronectin-binding integrin (green) produces a yellow fluorescence. (b) Electron micrograph of the junction of fibronectin and actin fibers in a cultured fibroblast. Individual actin-containing 7-nm microfilaments, components of a stress fiber, end at the obliquely sectioned cell membrane. The microfilaments appear aligned in close proximity to the thicker, densely stained fibronectin fibrils on the outside of the cell. [Part (a) from J. Duband et al., 1988, *J. Cell Biol.* **107**:1385. Part (b) from I. J. Singer, 1979, *Cell* **16**:675; courtesy of I. J. Singer; copyright 1979, MIT.]

integrin-binding fibronectin type III repeat and its neighboring type III domain, the RGD sequence is at the apex of a loop that protrudes outward from the molecule, in a position facilitating binding to integrins (Figure 20-32b). Although the RGD sequence is required for binding to several integrins, its affinity for integrins is substantially less than that of intact fibronectin or of the entire cell-binding region in fibronectin. Thus structural features near the RGD sequence in fibronectins (e.g., parts of adjacent repeats, such as the synergy region; see Figure 20-32b) and in other RGD-containing proteins enhance their binding to certain integrins. Moreover, the simple soluble dimeric forms of fibronectin produced by the liver or fibroblasts are initially in a nonfunctional conformation that binds poorly to integrins because the RGD sequence is not readily accessible. The adsorption of fibronectin to a collagen matrix or the basal lamina or, experimentally, to a plastic tissue-culture dish results in a conformational change that enhances the ability of fibronectin to bind to cells. Possibly, this conformational change increases the accessibility of the RGD sequence for integrin binding.

Microscopy and other experimental approaches (e.g., biochemical binding experiments) have demonstrated the role of integrins in cross-linking fibronectin and other ECM components to the cytoskeleton. For example, the colocalization of cytoskeletal actin filaments and integrins within cells can be visualized by fluorescence microscopy (Figure 20-34a). The binding of cell-surface integrins to fibronectin in the matrix induces the actin-cytoskeleton-dependent movement of some integrin molecules in the plane of the membrane. The ensuing mechanical tension due to the relative movement of different integrins bound to a single fibronectin dimer stretches the fibronectin. This stretching promotes self-association of fibronectins into multimeric fibrils.

The force needed to unfold and expose functional self-association sites in fibronectin is much less than that needed to

disrupt fibronectin-integrin binding. Thus fibronectin molecules remain bound to integrin while cell-generated mechanical forces induce fibril formation. In effect, the integrins through adapter proteins transmit the intracellular forces generated by the actin cytoskeleton to extracellular fibronectin (inside-out signaling). Gradually, the initially formed fibronectin fibrils mature into highly stable matrix components by covalent cross-linking. In some electron micrographic images, exterior fibronectin fibrils appear to be aligned in a seemingly continuous line with bundles of actin fibers within the cell (Figure 20-34b). These observations and the results from other studies provided the first example of a molecularly well-defined adhesion receptor forming a bridge between the intracellular cytoskeleton and the extracellular matrix components—a phenomenon now known to be widespread.

Elastic Fibers Permit Many Tissues to Undergo Repeated Stretching and Recoiling

Elastic fibers are found in the ECM of a wide variety of tissues (Figure 20-35a) that are subject to mechanical strain or deformation, such as lung expansion and contraction during breathing, the pulsatile flow of blood through blood vessels due to the heartbeat, and the stretching and contraction of skin. Elastic fibers permit the reversible elastic stretching and recoiling of these tissues.

FIGURE 20-35 Elastic and collagen fibers in connective tissue.

(a) Light-microscopic view of loose connective tissue from the lung. Elastic fibers are the thin fibers that are stained purple, collagen fibers (bundles of collagen fibrils) are stained pink, and the nuclei of cells are stained purple. (b) Longitudinal and (c) cross-sectional electron-microscopic views of elastic fibers and collagen fibrils (coll) in the skin of a mouse. The elastic fibers have a solid core of elastin (e) integrated into and surrounded by a bundle of microfibrils (mf). Scale bars, 0.25 μm . [Part (a) from Science Photo Library; parts (b) and (c) from J. Choi et al., 2009, *Matrix Biol.* 28:211–220.]

The major component of an elastic fiber, which can be several hundred to several thousand nm in diameter, is an insoluble, amorphous core composed of the protein *elastin* surrounded by a collection of 10–12 nm diameter *microfibrils* made up of proteins fibrillin, fibulin, and associated proteins (Figure 20-35b). The core is formed by the aggregation of *tropoelastin* molecules, elastin monomers that are covalently cross-linked via a lysyl-oxidase-mediated process similar to that seen in collagen. Repetitive proline- and glycine-enriched hydrophobic sequence motifs contribute to the ability of tropoelastins to self-associate and recoil efficiently after stretching.

 A variety of diseases, often involving skeletal and cardiovascular abnormalities, are consequences of mutations in the genes encoding the structural proteins of elastic fibers or the proteins that contribute to their proper assembly. For example, mutations in the fibrillin-1 gene cause Marfan syndrome, whose varied symptoms can include bone overgrowth, loose joints, abnormally long extremities and face, and cardiovascular defects due to weakness in the walls of vessels and the aorta. There has been considerable speculation that President Abraham Lincoln's unusually tall, elongated body may have been a consequence of Marfan syndrome. ■

In mammals, the synthesis of most tropoelastin only occurs immediately before and after birth during the late fetal and neonatal periods. Thus, most of the body's elastin must be very durable, lasting an entire lifetime. The extraordinary stability

of elastin has been measured in a variety of ways. Pulse-chase experiments (see Chapter 3) using radioactive amino acid administration can be used to measure the lifetime of elastin in animals. In humans, two other methods were employed to study the longevity of elastin and revealed that the mean lifetime of an elastin molecule in human lungs is about 70 years! The first method takes advantage of a naturally occurring phenomenon: the slow, natural rate of conversion of L-aspartic acid—incorporated into proteins during their synthesis—to D-aspartic acid. Thus the age of a long-lived protein can be estimated using chemical analysis to determine the fraction of its L-aspartic acid that has been converted over time to the D isomer, together with knowledge of the age of the tissue from which it was isolated. The second method is a variation on the classical pulse-chase experiments used in the laboratory. As a consequence of nuclear weapons testing in the 1950s and 1960s, ^{14}C was introduced into the atmosphere and hence the food chain. This environmental ^{14}C has been used as the radioactive “pulse” in what is essentially a pulse-chase experiment to determine the stability of proteins of interest.

Metalloproteases Remodel and Degrade the Extracellular Matrix

Many key physiologic processes, including tissue morphogenesis during development, control of cellular proliferation and motility, response to injury, and even survival, require not only the production of ECM but also its remodeling or degradation. Because of its enormous importance as a key element in the extracellular microenvironment of multicellular organisms, remodeling/degradation of the ECM must be carefully controlled. Degradation of the ECM is often mediated by zinc-dependent **matrix metalloproteases (MMPs)**. Given the wide array of ECM components, it is not surprising that there are many such metalloproteases with varying substrate specificities and sites of expression. In many cases their names incorporate the names of their substrates, as for the MMPs called collagenases, gelatinases, elastases, and aggrecanases. Some are secreted into the extracellular fluid, and others are closely associated with the plasma membranes of cells, either tightly bound in a noncovalent association with the membrane or as integral membrane proteins. Many are initially synthesized as inactive precursors that must be specifically activated to function.

There are three major subgroups of ECM proteases based on the enzymes' structures: MMPs (of which there are 23 in humans), a disintegrin and metalloproteinases (ADAMs), and ADAM with thrombospondin motifs (ADAMTSs). These proteases can degrade ECM components as well as non-ECM components such as surface-adhesion receptors. Indeed, a key function of ADAMs is cleaving extracellular domains from integral membrane protein substrates. One mechanism used to control the activities of these proteases is the production of protein inhibitors called TIMPs (tissue inhibitors of metalloproteinases) and RECK (reversion-inducing-cysteine-rich protein with kazal motifs). Some of these have their own cell-surface receptors and functions independent of their ability to inhibit metalloproteinases. ECM-degrading proteases are

associated with a variety of diseases, the best known of which is metastatic (spreading) cancer (see Chapter 24).

KEY CONCEPTS of Section 20.4

The Extracellular Matrix II: Connective Tissue

- Connective tissue, such as tendon and cartilage, differs from other solid tissues in that most of its volume is made up of extracellular matrix (ECM) rather than cells.
- The synthesis of fibrillar collagen (e.g., types I, II, and III) begins inside the cell with the chemical modification of newly made α chains and their assembly into triple-helical procollagen within the endoplasmic reticulum. After secretion, procollagen molecules are cleaved, associate laterally, and are covalently cross-linked into bundles called fibrils, which can form larger assemblies called fibers (see Figure 20-26).
- The various collagens are distinguished by the ability of their helical and nonhelical regions to associate into fibrils, to form sheets, or to cross-link other collagen types (see Table 20-4).
- Proteoglycans consist of membrane-associated or secreted core proteins covalently linked to one or more glycosaminoglycan (GAG) chains, which are linear polymers of disaccharides that are often modified by sulfation.
- Cell-surface proteoglycans such as the syndecans facilitate cell-matrix interactions and help present certain external signaling molecules to their cell-surface receptors.
- Hyaluronan, a highly hydrated GAG, is a major component of the ECM of migrating and proliferating cells. Certain cell-surface adhesion receptors bind hyaluronan to cells.
- Large proteoglycan aggregates containing a central hyaluronan molecule noncovalently bound to the core protein of proteoglycan molecules (e.g., aggrecan) contribute to the ability of the matrix to resist compressive forces (see Figure 20-31).
- Fibronectins are abundant multi-adhesive matrix proteins that play a key role in migration and cellular differentiation. They contain binding sites for integrins and ECM components (collagens, proteoglycans) and thus can attach cells to the matrix (see Figure 20-32).
- The tripeptide RGD sequence Arg-Gly-Asp, found in fibronectins and some other matrix proteins, is recognized by several integrins.
- Elastic fibers permit repeated stretching and recoiling of tissues because of their highly elastic core of cross-linked, amorphous elastin, which is surrounded by a network of microfibrils.
- The remodeling/degradation of ECM is often mediated by a large number of secreted and cell-membrane-associated zinc metalloproteases that fall into several families (MMPs, ADAMs, ADAMTSs) and whose activities are regulated by activation and by protein inhibitors (TIMPs and RECK).

20.5 Adhesive Interactions in Motile and Nonmotile Cells

After adhesive interactions in epithelia form during differentiation, they often are very stable and can last throughout the life span of the cells or until the epithelium undergoes further differentiation. Although such long-lasting (nonmotile) adhesion also exists in nonepithelial tissues, some nonepithelial cells must be able to crawl across or through a layer of extracellular matrix or other cells. Moreover, during development or wound healing and in certain pathologic states (e.g., cancer), epithelial cells can transform into more motile cells (the epithelial-mesenchymal transition). Changes in expression of adhesive molecules play a key role in this transformation, as they do in other biological processes involving cell movement, such as the crawling of white blood cells into tissue sites of infection. In this section, we describe various cell-surface structures that mediate transient adhesive interactions that are especially adapted for the movement of cells as well as those that mediate long-lasting adhesion. The detailed intracellular mechanisms used to generate the mechanical forces that propel cells and modify their shapes are covered in Chapters 17 and 18.

Integrins Relay Signals between Cells and Their Three-Dimensional Environment

As already discussed, integrins connect epithelial cells to the basal lamina and, through adapter proteins, to intermediate filaments of the cytoskeleton (see Figure 20-1). That is, integrins form a bridge between the ECM and cytoskeleton; they do the same in nonepithelial cells. In nonepithelial cells, integrins in the plasma membrane also are clustered with other molecules in various adhesive structures called focal adhesions, focal contacts, focal complexes, 3-D adhesions, and fibrillar adhesions, as well as in circular adhesions called podosomes. These structures are multiprotein complexes that are collectively called the integrin adhesome. These complexes mediate mechanosensory coupling between cells and their environments, and are readily observed by fluorescence microscopy with the use of antibodies that recognize integrins or other co-clustered molecules (Figure 20-36). As with cell-matrix anchoring junctions in epithelial cells, these various adhesive structures attach nonepithelial cells to the extracellular matrix through, for example, binding to fibronectin (see Figure 20-34). They also mediate integrin association with the actin cytoskeleton and activate adhesion-dependent signals for cell growth and cell motility (see Figure 20-8).

Integrin-containing adhesive structures are dynamic (components moving in and out constantly) and contain dozens of intracellular adapter and associated proteins (more than 190 identified to date) with the potential to engage in many hundreds (more than 740) of distinct protein-protein interactions that may be subject to regulation. For example, binding sites generated by phosphorylation of integrin and its

EXPERIMENTAL FIGURE 20-36 Integrins cluster into adhesive structures with various morphologies in nonepithelial cells. Immunofluorescence methods were used to detect adhesive structures (green) on cultured cells. Shown here are focal adhesions (a) and 3-D adhesions (b) on the surfaces of human fibroblasts. Cells were grown directly on the flat surface of a culture dish (a) or on a three-dimensional matrix of ECM components (b). The shape, distribution, and composition of the integrin-based adhesions formed by cells vary, depending on the cells' environment. [Part (a) from B. Geiger et al., 2001, *Nature Rev. Mol. Cell Biol.* 2:793; part (b) courtesy of K. Yamada and E. Cukierman; see E. Cukierman et al., 2001, *Science* 294:1708–1712.]

(a) Focal adhesion

(b) 3-D adhesion

associated proteins as well as by generation of phosphorylated derivatives of phosphatidylinositol in the adjacent membrane recruit additional proteins into and can also cause release of some proteins from these multiprotein complexes. There is a tightly controlled choreography of internal signals, contributions of other signaling pathways such as those involving receptor tyrosine kinases (see Figure 20-8), and external signals (such as rigidity of the ECM) that regulate these complexes. Together they help define the precise composition and activity of the integrin multiprotein complex and the consequent influence that it has on cellular structure and activity (outside-in effect) as well as the influence of the cellular actin cytoskeleton on the ECM (inside-out effect).

Although found in many nonepithelial cells, integrin-containing adhesive structures have been studied most frequently in fibroblasts grown in cell culture on flat glass or plastic surfaces called substrata. These conditions only poorly approximate the three-dimensional ECM environment that normally surrounds such cells in vivo. When fibroblasts are cultured in three-dimensional ECM matrices derived from cells or tissues, they form adhesions to the three-dimensional ECM substratum, called 3-D adhesions. These structures differ somewhat in composition, shape, distribution, and activity from the focal or fibrillar adhesions seen in cells growing on the flat substratum typically used in cell-culture experiments (see Figure 20-36). Cultured fibroblasts with these “more natural” anchoring junctions display greater adhesion and mobility, increased rates of cell proliferation, and spindle-shaped morphologies more like those of fibroblasts in tissues than do cells cultured on flat surfaces. These observations indicate that the topological, compositional, and mechanical properties of the extracellular matrix all play a role in controlling the shape and activity of a cell. Tissue-specific differences in these matrix characteristics probably contribute to the tissue-specific properties of cells.

The importance of the 3-D environment of cells has been highlighted by cell culture studies of the morphogenesis, functioning, and stability of specialized milk-producing mammary epithelial cells and their cancerously transformed

counterparts. For example, the 3-D matrix-dependent outside-in signaling mediated by integrins influences the epidermal growth-factor tyrosine-kinase-receptor signaling system and vice versa. The 3-D matrix also permits the mammary epithelial cells to generate in-vivo-like circular epithelial structures, called acini. Acini secrete the major protein constituents of milk and permit comparisons of the responses of normal and cancerous cells to potential chemotherapeutic agents. Analogous systems employing both natural and synthetic 3-D ECMs are being developed to provide more in-vivo-like conditions to study other complex tissues and organs, such as the liver.

Regulation of Integrin-Mediated Adhesion and Signaling Controls Cell Movement

Cells can exquisitely control the strength of integrin-mediated cell-matrix interactions by regulating integrin expression levels, ligand-binding activities, or both. Such regulation is critical to the role of these interactions in cell migration and other functions involving cell movement.

Integrin Binding Many, if not all, integrins can exist in two conformations: a low-affinity (inactive) form and a high-affinity (active) form (Figure 20-37a). The results of structural studies and experiments investigating the binding of ligands by integrins have provided a model of the changes that take place when integrins are activated. In the inactive state, the $\alpha\beta$ heterodimer is bent (Figure 20-37a, top; and 20-37c), the conformation of the ligand-binding site at the tip of the molecule allows only low-affinity ligand binding, and the transmembrane domains and cytoplasmic C-terminal tails of the two subunits are closely bound together. In the active state, subtle structural alterations in the conformation of the domains that form the binding site permit tighter (high-affinity) ligand binding and this is accompanied by separation of the transmembrane and cytoplasmic domains (Figure 20-37a, bottom). Activation is also accompanied by the straightening of the bent conformation into a more extended,

EXPERIMENTAL FIGURE 20-37 Model for integrin activation.

(a) Activation of integrins is thought to be due to conformational changes that include key movements near the propeller and βA domains, which increase the affinity for ligands. These are accompanied by straightening of the molecule from the inactive, low affinity, "bent" conformation (*top*) to the active, high affinity, "extended" conformation (*bottom*). Activation also involves separation (indicated by double-headed arrow, *bottom*) of the transmembrane and cytoplasmic domains, induced by or resulting in altered interactions with adaptor proteins talin and kindlin, whose sites of binding to the cytoplasmic tail of the β chain are indicated by green and yellow ovals, respectively. (b) Single inactive (bent) integrin $\alpha IIb\beta 3$ molecules (*top* panel) were incorporated into phospholipid nanodiscs (small bilayers in which the extracellular and cytoplasmic domains of the integrin are exposed to the buffer) and to some of these (*bottom* panel) were

added the integrin-binding and activating "head" domain of the adaptor protein talin. Multiple electron microscopic images of individual discs were collected and averaged. Phospholipid nanodiscs are indicated by dashed white circles, the heights of the integrin extracellular regions that extend above the nanodiscs are indicated by brackets. (c) A molecular model of the extracellular region of $\alpha v\beta 3$ integrin in its inactive, low-affinity ("bent") form, with the α subunit in shades of blue and the β subunit in shades of red is based on the x-ray crystal structure. The major ligand-binding sites are at the tip of the molecule, where the propeller domain of the α subunit (dark blue) and βA domain (dark red) interact. An RGD peptide ligand is shown in yellow. [Adapted from M. Arnaout et al., 2002, *Curr. Opin. Cell Biol.* **14**:641; R. O. Hynes, 2002, *Cell* **110**:673; Feng Ye et al. 2010, *J CELL BIOL.* **188**:157–73; and M. Moser et al., 2009, *Science* **324**:895–899.]

linear form in which the ligand-binding site is projected farther away from the surface of the membrane (see Figure 20-37).

These structural models provide an attractive explanation for the ability of integrins to mediate outside-in and inside-out signaling. The binding of certain ECM molecules or CAMs on other cells to the integrin's extracellular ligand-binding site would hold the integrin in the active form with separated cytoplasmic tails. Intracellular adapters could "sense" the separation of the tails and, as a result, either bind to or dissociate from the tails. The changes in these adapters could then alter the cytoskeleton and activate or inhibit intracellular signaling pathways. Conversely, changes in the metabolic/signaling state of the cells could cause intracellular adapters to bind to or dissociate from the cytoplasmic tails of integrins and thus force the tails to either separate or associate. As a consequence, the integrin would either bend (inactivate) or straighten (activate), thereby altering its interaction with the ECM or other cells. Indeed, *in vitro* studies of purified integrins reconstituted individually into lipid bilayer "nanodiscs" show that binding of the globular domain of the

adaptor protein *talin* to the cytoplasmic tail of integrin's β chain is sufficient to activate integrin, inducing an extension of the bent conformation to an extended, active form (Figure 20-37a, *bottom*; and 20-37b, *bottom*). Other studies suggest that the efficient activation of integrins in intact cells may also require the participation of another class of adaptor proteins called *kindlins*, which bind to a distinct site on the cytoplasmic tail of integrin's β chain (see Figure 20-37 a, *bottom*).

Platelet function, discussed in more detail below, provides a good example of how cell-matrix interactions are modulated by controlling integrin binding activity. Platelets are cell fragments that circulate in the blood and clump together with ECM molecules to form a blood clot. In its basal state, the $\alpha IIb\beta 3$ integrin present on the plasma membranes of platelets normally cannot bind tightly to its protein ligands (including fibrinogen and fibronectin), all of which participate in the formation of a blood clot, because it is in the inactive (bent) conformation. During clot formation, platelets bind to ECM proteins such as collagen and a large protein called von Willebrand factor through receptors that generate intracellular

signals. Platelets may also be activated by ADP or the clotting enzyme thrombin. These signals induce changes in signaling pathways in the cytoplasm that result in an activating conformational change in the platelet's $\alpha\text{IIb}\beta_3$ integrin. As a consequence, this integrin can then tightly bind to extracellular clotting proteins and participate in clot formation. People with genetic defects in the β_3 integrin subunit are prone to excessive bleeding, attesting to the role of the $\alpha\text{IIb}\beta_3$ integrin in the formation of blood clots (see Table 20-3).

Integrin Expression The attachment of cells to ECM components can also be modulated by altering the number of integrin molecules exposed on the cell surface. The $\alpha_4\beta_1$ integrin, which is found on many hematopoietic cells, offers an example of this regulatory mechanism. For these hematopoietic cells to proliferate and differentiate, they must be attached to fibronectin synthesized by supportive (stromal) cells in the bone marrow. The $\alpha_4\beta_1$ integrin on hematopoietic cells binds to a Glu-Ile-Leu-Asp-Val (EILDV) sequence in fibronectin, thereby anchoring the cells to the matrix. This integrin also binds to a sequence in a CAM called vascular CAM-1 (VCAM-1), which is present on stromal cells of the bone marrow. Thus hematopoietic cells directly contact the stromal cells as well as attach to the matrix. Late in their differentiation, hematopoietic cells decrease their expression of this integrin; the resulting reduction in the number of $\alpha_4\beta_1$ integrin molecules on the cell surface is thought to allow mature blood cells to detach from the matrix and stromal cells in the bone marrow and subsequently enter the circulation.

Connections Between the ECM and Cytoskeleton Are Defective in Muscular Dystrophy

The importance of the adhesion-receptor-mediated linkage between ECM components and the cytoskeleton is highlighted by a set of hereditary muscle-wasting diseases, collectively called muscular dystrophies. Duchenne muscular dystrophy (DMD), the most common type, is a sex-linked disorder, affecting 1 in 3300 boys, that results in cardiac or respiratory failure, usually in the late teens or early twenties. The first clue to understanding the molecular basis of this disease came from the discovery that people with DMD carry mutations in the gene encoding a protein named *dystrophin*. This very large protein was found to be a cytosolic adapter protein, binding to actin filaments and to an adhesion receptor called *dystroglycan* (Figure 20-38).

Dystroglycan is synthesized as a large glycoprotein precursor that is proteolytically cleaved into two subunits soon after it is synthesized and before it moves to the cell surface. The α subunit is a peripheral membrane protein, and the β subunit is a transmembrane protein whose extracellular domain associates with the α subunit (Figure 20-38). Multiple O-linked oligosaccharides are attached covalently to side-chain hydroxyl groups of serine and threonine residues in the α subunit. Unlike the most abundant O-linked, also called mucin-like, oligo-

FIGURE 20-38 Dystrophin glycoprotein complex (DGC) in skeletal muscle cells. This schematic model shows that the DGC comprises three subcomplexes: the α,β dystroglycan subcomplex; the sarcoglycan/sarcospan subcomplex of integral membrane proteins; and the cytosolic adapter subcomplex comprising dystrophin, other adapter proteins, and signaling molecules. Through its O-linked sugars, β -dystroglycan binds to components of the basal lamina, such as laminin and perlecan, and cell-surface proteins, such as neurexin in neurons. Dystrophin—the protein defective in Duchenne muscular dystrophy—links β -dystroglycan to the actin cytoskeleton, and α -dystrobrevin links dystrophin to the sarcoglycan/sarcospan subcomplex. Nitric oxide synthase (NOS) produces nitric oxide, a gaseous signaling molecule, and GRB2 is a component of signaling pathways activated by certain cell-surface receptors (see Chapter 15). [Adapted from S. J. Winder, 2001, *Trends Biochem. Sci.* **26**:118, and D. E. Michele and K. P. Campbell, 2003, *J. Biol. Chem.* **278**(18):15457–15460.]

saccharides, in which an N-acetylgalactosamine (GalNAc) is the first sugar in the chain linked directly to the hydroxyl group of the side chain of serine or threonine (Figure 20-29b) or the linkage in proteoglycans (Figure 20-29a), many of the O-linked chains in dystroglycan are directly linked to the hydroxyl group via a mannose sugar (see Figure 20-29c).

These specialized O-linked oligosaccharides bind to various basal lamina components, including the LG domains of the multi-adhesive matrix protein laminin and the proteoglycans perlecan and agrin. The neurexins, a family of adhesion molecules expressed by neurons, also are bound via these specialized oligosaccharides, whose detailed heterogeneous structures and mechanisms of synthesis have not been fully elucidated.

The transmembrane segment of the dystroglycan β subunit associates with a complex of integral membrane proteins; its cytosolic domain binds dystrophin and other adapter proteins as well as various intracellular signaling proteins (see Figure 20-38). The resulting large, heteromeric assemblage, the *dystrophin glycoprotein complex* (DGC), links the extracellular matrix to the cytoskeleton and signaling pathways within muscle and other types of cells. For instance, the signaling

enzyme nitric oxide synthase (NOS) is associated through syntrophin with the cytosolic dystrophin subcomplex in skeletal muscle. The rise in intracellular Ca^{2+} during muscle contraction activates NOS to produce nitric oxide (NO), a signaling molecule that diffuses into smooth muscle cells surrounding nearby blood vessels. NO promotes smooth muscle relaxation, leading to a local rise in the flow of blood supplying nutrients and oxygen to the skeletal muscle.

Mutations in dystrophin, other DGC components, laminin, or enzymes that add the O-linked sugars to dystroglycan can all disrupt the DGC-mediated link between the exterior and the interior of muscle cells and cause muscular dystrophies. In addition, dystroglycan mutations have been shown to greatly reduce the clustering of acetylcholine receptors on muscle cells at the neuromuscular junctions, which is also dependent on the basal lamina proteins laminin and agrin. These and possibly other effects of DGC defects apparently lead to a cumulative weakening of the mechanical stability of muscle cells as they undergo contraction and relaxation, resulting in deterioration of the cells and muscular dystrophy.

Dystroglycan provides an elegant—and medically relevant—example of the intricate networks of connectivity in cell biology. Dystroglycan was originally discovered in the context of studying DMD. However, it was later shown to be expressed in nonmuscle cells and, through its binding to laminin, to play a key role in the assembly and stability of at least some basement membranes. Thus it is essential for normal development. Additional studies led to its identification as a cell-surface receptor for the virus that causes the frequently fatal human disease Lassa fever and other related viruses, all of which bind via the same specialized O-linked sugars that mediate binding to laminin. Furthermore, dystroglycan is also the receptor on specialized cells in the nervous system—Schwann cells—to which binds the pathogenic bacterium *Mycobacterium leprae*, the organism that causes leprosy. ■

IgCAMs Mediate Cell-Cell Adhesion in Neuronal and Other Tissues

Numerous transmembrane proteins characterized by the presence of multiple immunoglobulin domains in their extracellular regions constitute the immunoglobulin (Ig) superfamily of CAMs, or IgCAMs. The Ig domain is a common protein domain, containing 70–110 residues, that was first identified in antibodies, the antigen-binding immunoglobulins, but has a much older evolutionary origin in CAMs. The human, *D. melanogaster*, and *C. elegans* genomes include about 765, 150, and 64 genes, respectively, that encode proteins containing Ig domains. Immunoglobulin domains are found in a wide variety of cell-surface proteins, including T-cell receptors produced by lymphocytes and many proteins that take part in adhesive interactions. Among the IgCAMs are neural CAMs; intercellular CAMs (ICAMs), which function in the movement of leukocytes into tissues; and junction adhesion molecules (JAMs), which are present in tight junctions.

As their name implies, neural CAMs are of particular importance in neural tissues. One type, the NCAMs, primar-

ily mediate homophilic interactions. First expressed during morphogenesis, NCAMs play an important role in the differentiation of muscle, glial, and nerve cells. Their role in cell adhesion has been directly demonstrated by the inhibition of adhesion with anti-NCAM antibodies. Numerous NCAM isoforms, encoded by a single gene, are generated by alternative mRNA splicing and by differences in glycosylation. Other neural CAMs (e.g., L1-CAM) are encoded by different genes. In humans, mutations in different parts of the L1-CAM gene cause various neuropathologies (e.g., mental retardation, congenital hydrocephalus, and spasticity).

An NCAM comprises an extracellular region with five Ig domains and two fibronectin type III domains, a single membrane-spanning segment, and a cytosolic segment that interacts with the cytoskeleton (see Figure 20-2). In contrast, the extracellular region of L1-CAM has six Ig domains and four fibronectin type III domains. As with cadherins, cis (intracellular) interactions and trans (intercellular) interactions probably play key roles in IgCAM-mediated adhesion (see Figure 20-3); however, adhesion mediated by IgCAMs is Ca^{2+} independent.

The covalent attachment of multiple chains of sialic acid, a negatively charged sugar derivative, to NCAMs alters their adhesive properties. In embryonic tissues such as brain, polysialic acid constitutes as much as 25 percent of the mass of NCAMs. Possibly because of repulsion between the many negatively charged sugars in these NCAMs, cell-cell contacts are fairly transient, being made and then broken, a property necessary for the development of the nervous system. In contrast, NCAMs from adult tissues contain only one-third as much sialic acid, permitting more stable adhesions.

Leukocyte Movement into Tissues Is Orchestrated by a Precisely Timed Sequence of Adhesive Interactions

In adult organisms, several types of white blood cells (leukocytes) participate in the defense against infection caused by bacteria and viruses or by tissue damage due to trauma or inflammation. To fight infection and clear away damaged tissue, these cells must move rapidly from the blood, where they circulate as unattached, relatively quiescent cells, into the underlying tissue at sites of infection, inflammation, or damage. We know a great deal about the movement into tissue, termed *extravasation*, of four types of leukocytes: neutrophils, which release several antibacterial proteins; monocytes, the precursors of macrophages, which can engulf and destroy foreign particles; and T and B lymphocytes, the antigen-recognizing cells of the immune system (see Chapter 23).

Extravasation requires the successive formation and breakage of cell-cell contacts between leukocytes in the blood and endothelial cells lining the vessels. Some of these contacts are mediated by *selectins*, a family of CAMs that mediate leukocyte-vascular cell interactions. A key player in these interactions is *P-selectin*, which is localized on the blood-facing surface of endothelial cells. All selectins contain a Ca^{2+} -dependent *lectin domain*, which is located at the distal end of the extracellular region of the molecule and recognizes

FIGURE 20-39 Endothelium-leukocyte interactions: activation, binding, rolling, and extravasation. Step **1**: In the absence of inflammation or infection, leukocytes and endothelial cells lining blood vessels are in a resting state. Step **2**: Inflammatory signals released only in areas of inflammation, infection, or both activate resting endothelial cells to move vesicle-sequestered selectins to the cell surface. The exposed selectins mediate weak binding of leukocytes by interacting with carbohydrate ligands on leukocytes. Blood flow forces the loosely bound leukocytes to roll along the endothelial surface of the blood vessel. Activation of the endothelium also causes synthesis

of platelet-activating factor (PAF) and ICAM-1, both expressed on the cell surface. PAF and other usually secreted activators, including chemokines, then induce changes in the shapes of the leukocytes and activation of leukocyte integrins such as $\alpha L\beta 2$, which is expressed by T lymphocytes (step **3**). The subsequent tight binding between activated integrins on leukocytes and CAMs on the endothelium (e.g., ICAM-2 and ICAM-1) results in firm adhesion (step **4**) and subsequent movement (extravasation) into the underlying tissue (step **5**). [Adapted from R. O. Hynes and A. Lander, 1992, *Cell* **68**:303.]

particular sugars in glycoproteins or glycolipids (see Figure 20-2). For example, the primary ligand for P- and E-selectins is an oligosaccharide called the *sialyl Lewis-x antigen*, a part of longer oligosaccharides present in abundance on leukocyte glycoproteins and glycolipids.

Figure 20-39 illustrates the basic sequence of cell-cell interactions leading to the extravasation of leukocytes. Various inflammatory signals released in areas of infection or inflammation first cause activation of the endothelium. P-selectin exposed on the surface of activated endothelial cells mediates the weak adhesion of passing leukocytes. Because of the force of the blood flow and the rapid “on” and “off” rates of P-selectin binding to its ligands, these “trapped” leukocytes are slowed but not stopped and literally roll along the surface of the endothelium. Among the signals that promote activation of the endothelium are chemokines, a group of small secreted proteins (8–12 kDa) produced by a wide variety of cells, including endothelial cells and leukocytes.

For tight adhesion to occur between activated endothelial cells and leukocytes, $\beta 2$ -containing integrins on the surfaces

of leukocytes also must be activated indirectly by chemokines or other local activation signals such as *platelet-activating factor* (PAF). Platelet-activating factor is unusual in that it is a phospholipid rather than a protein; it is exposed on the surface of activated endothelial cells at the same time that P-selectin is exposed. The binding of PAF or other activators to their *G protein-coupled* receptors on leukocytes leads to activation of the leukocyte integrins to their high-affinity form (see Figure 20-37). Activated integrins on leukocytes then bind to distinct IgCAMs on the surface of endothelial cells. These include ICAM-2, which is expressed constitutively, and ICAM-1. ICAM-1, whose synthesis is induced by activation, does not usually contribute substantially to leukocyte endothelial cell adhesion immediately after activation but rather participates at later times in cases of chronic inflammation. The resulting tight adhesion mediated by the Ca^{2+} -independent-integrin-ICAM interactions leads to the cessation of rolling and to the spreading of leukocytes on the surface of the endothelium; soon the adhered cells move between adjacent endothelial cells and into the underlying tissue. The extravasation step

itself (also called *transmigration* or *diapedesis*; step 5 in Figure 20-39) requires the dissociation of otherwise stable adhesive interactions between endothelial cells that are primarily mediated by the CAM VE-cadherin. There is general agreement that the leukocyte interactions with the endothelial cells initiates outside-to-inside signaling in the endothelial cells that weakens or disrupts their VE-cadherin-mediated adhesions, permitting the paracellular movement of the leukocyte. Mechanical forces and other mechanisms may also be involved.

The selective adhesion of leukocytes to the endothelium near sites of infection or inflammation thus depends on the sequential appearance and activation of several different CAMs on the surfaces of the interacting cells. Different types of leukocytes express different integrins, though all contain the $\beta 2$ subunit. Nonetheless, all leukocytes move into tissues by the same general mechanism depicted in Figure 20-39.

Many of the CAMs used to direct leukocyte adhesion are shared among different types of leukocytes and target tissues. Yet often only a particular type of leukocyte is directed to a particular tissue. How is this specificity achieved? A three-step model has been proposed to account for the cell-type specificity of such leukocyte–endothelial-cell interactions. First, endothelial activation promotes initial relatively weak, transient, and reversible binding (e.g., the interaction of selectins and their carbohydrate ligands). Without additional local activation signals, the leukocyte will quickly move on. Second, cells in the immediate vicinity of the site of infection or inflammation release or express chemical signals such as chemokines and PAF that activate only special subsets of the transiently attached leukocytes, depending on the types of chemokine receptors they express. Third, additional activation-dependent CAMs (e.g., integrins) engage their binding partners, leading to strong sustained adhesion. Only if the proper combination of CAMs, binding partners, and activation signals are engaged together with the appropriate timing at a specific site will a given leukocyte adhere strongly. Such combinatorial diversity and cross talk allows a small set of CAMs to serve diverse functions throughout the body—a good example of biological parsimony.

 **Leukocyte-adhesion deficiency** is caused by a genetic defect in the synthesis of the integrin $\beta 2$ subunit. People with this disorder are susceptible to repeated bacterial infections because their leukocytes cannot extravasate properly and thus fight infection within a tissue.

Some pathogenic viruses have evolved mechanisms to exploit cell-surface proteins that participate in the normal response to inflammation. For example, many of the RNA viruses that cause the common cold (rhinoviruses) bind to and enter cells through ICAM-1, and chemokine receptors can be important entry sites for human immunodeficiency virus (HIV), the cause of AIDS. Integrins appear to participate in the binding and/or internalization of a wide variety of viruses, including reoviruses (causing fever and gastroenteritis, especially in infants), adenoviruses (causing conjunctivitis, acute respiratory disease), and foot-and-mouth-disease virus (causing fever in cattle and pigs). ■

KEY CONCEPTS of Section 20.5

Adhesive Interactions in Motile and Nonmotile Cells

- Many cells have integrin-containing aggregates (e.g., focal adhesions, 3-D adhesions, podosomes) that physically and functionally connect cells to the extracellular matrix and facilitate inside-out and outside-in signaling.
- Via interaction with integrins, the three-dimensional structure of the ECM surrounding a cell can profoundly influence the behavior of the cell.
- Integrins exist in two conformations (bent-inactive, straight-active) that differ in the affinity for ligands and interactions with cytosolic adapter proteins (see Figure 20-37); switching between these two conformations allows regulation of integrin activity, which is important for control of cell adhesion and movements.
- Dystroglycan, an adhesion receptor, forms a large complex with dystrophin, other adapter proteins, and signaling molecules (see Figure 20-38). This complex links the actin cytoskeleton to the surrounding matrix, providing mechanical stability to muscle. Mutations in various components of this complex cause different types of muscular dystrophy.
- Neural cell-adhesion molecules, which belong to the immunoglobulin (Ig) family of CAMs, mediate Ca^{2+} -independent cell-cell adhesion in neural and other tissues.
- The combinatorial and sequential interaction of several types of CAMs (e.g., selectins, integrins, and ICAMs) is critical for the specific and tight adhesion of different types of leukocytes to endothelial cells in response to local signals induced by infection or inflammation (see Figure 20-39).

20.6 Plant Tissues

We turn now to the assembly of plant cells into tissues. The overall structural organization of plants is generally simpler than that of animals. For instance, plants have only four broad types of cells, which in mature plants form four basic classes of tissue: *dermal tissue* interacts with the environment, *vascular tissue* transports water and dissolved substances such as sugars and ions, space-filling *ground tissue* constitutes the major sites of metabolism, and *sporogenous tissue* forms the reproductive organs. Plant tissues are organized into just four main organ systems: *stems* have support and transport functions, *roots* provide anchorage and absorb and store nutrients, *leaves* are the sites of photosynthesis, and *flowers* enclose the reproductive structures. Thus at the cell, tissue, and organ levels, plants are generally less complex than most animals.

Moreover, unlike animals, plants do not replace or repair old or damaged cells or tissues; they simply grow new organs. Indeed, the developmental fate of any given plant cell is primarily based on its position in the organism rather than its lineage (see Chapter 21), whereas both are important in animals. Thus in both plants and animals a cell's direct communication with its neighbors is important. Most importantly

FIGURE 20-40 Structure of the plant cell wall. (a) Overview of the organization of a typical plant cell, in which the organelle-filled cell with its plasma membrane is surrounded by a well-defined extracellular matrix called the cell wall. (b) Schematic representation of the cell wall of an onion. Cellulose and hemicellulose are arranged into at least three layers in a matrix of pectin polymers. The size of the polymers and their separations are drawn to scale. To simplify the diagram, most of the hemicellulose cross-links and other matrix constituents

(e.g., extensin, lignin) are not shown. (c) Fast-freeze, deep-etch electron micrograph of the cell wall of the garden pea in which some of the pectin polysaccharides were removed by chemical treatment. The abundant thicker fibers are cellulose microfibrils, and the thinner fibers are hemicellulose cross-links (red arrowheads). [Part (b) adapted from M. McCann and K. R. Roberts, 1991, in C. Lloyd, ed., *The Cytoskeletal Basis of Plant Growth and Form*, Academic Press, p. 126, as modified in C. Somerville et al. Part (c) from T. Fujino and T. Itoh, 1998, *Plant Cell Physiol.* **39**:1315–1323.]

for this chapter and in contrast with animals, few cells in plants directly contact one another through molecules incorporated into their plasma membranes. Instead, plant cells are typically surrounded by a rigid cell wall that contacts the cell walls of adjacent cells (Figure 20-40a). Also in contrast with animal cells, a plant cell rarely changes its position in the organism relative to other cells. These features of plants and their organization have determined the distinctive molecular mechanisms by which plants' cells are incorporated into tissues and communicate with one another.

The Plant Cell Wall Is a Laminate of Cellulose Fibrils in a Matrix of Glycoproteins

The plant extracellular matrix, or cell wall, which is mainly composed of polysaccharides and is $\sim 0.2 \mu\text{m}$ thick, completely coats the outside of the plant cell's plasma membrane. This structure serves some of the same functions as those of the ECM produced by animal cells, even though the two structures are composed of entirely different macromolecules and have a different organization. About 1000 genes in the plant *Arabidopsis*, a small flowering plant also called "thale cress" (see Chapters 1 and 6), are devoted to the synthesis and functioning of its cell wall, including approximately 414 glycosyltransferase and more than 316 glycosyl hydrolase genes. Like animal-cell ECM, the plant cell wall connects cells into tissues, signals a plant cell to grow and divide, and controls the shape of plant organs. It is a dynamic structure that plays important roles in controlling the differentiation of plant cells during embryogenesis and growth and provides a barrier to protect against pathogen infection. Just as the extracellular

matrix helps define the shapes of animal cells, the cell wall defines the shapes of plant cells. When the cell wall is digested away from plant cells by hydrolytic enzymes, spherical cells enclosed by a plasma membrane are left.

Because a major function of a plant cell wall is to withstand the osmotic turgor pressure of the cell (between 14.5 and 435 pounds per square inch!), the cell wall is built for lateral strength. It is arranged into layers of cellulose microfibrils—bundles of 30–36 chains of long (as much as $7 \mu\text{m}$ or greater), linear, extensively hydrogen-bonded polymers of glucose in β glycosidic linkages. The cellulose microfibrils are embedded in a matrix composed of pectin, a polymer of D-galacturonic acid and other monosaccharides, and hemicellulose, a short, highly branched polymer of several five- and six-carbon monosaccharides. The mechanical strength of the cell wall depends on cross-linking of the microfibrils by hemicellulose chains (Figure 20-40b, c). The layers of microfibrils prevent the cell wall from stretching laterally. Cellulose microfibrils are synthesized on the exoplasmic face of the plasma membrane from UDP-glucose and ADP-glucose formed in the cytosol. The polymerizing enzyme, called cellulose synthase, moves within the plane of the plasma membrane along tracks of intracellular microtubules as cellulose is formed, providing a distinctive mechanism for intracellular/extracellular communication.

Unlike cellulose, pectin and hemicellulose are synthesized in the Golgi apparatus and transported to the cell surface, where they form an interlinked network that helps bind the walls of adjacent cells to one another and cushions them. When purified, pectin binds water and forms a gel in the presence of Ca^{2+} and borate ions—hence the use of pectins in

many processed foods. As much as 15 percent of the cell wall may be composed of *extensin*, a glycoprotein that contains abundant hydroxyproline and serine. Most of the hydroxyproline residues are linked to short chains of arabinose (a five-carbon monosaccharide), and the serine residues are linked to galactose. Carbohydrate accounts for about 65 percent of extensin by weight, and its protein backbone forms an extended rodlike helix with the hydroxyl or O-linked carbohydrates protruding outward. *Lignin*—a complex, insoluble polymer of phenolic residues—associates with cellulose and is a strengthening material. Like cartilage proteoglycans, lignin resists compression forces on the matrix.

The cell wall is a selective filter whose permeability is controlled largely by pectins in the wall matrix. Whereas water and ions diffuse freely across cell walls, the diffusion of large molecules, including proteins larger than 20 kDa, is limited. This limitation may account for why many plant hormones are small, water-soluble molecules, which can diffuse across the cell wall and interact with receptors in the plasma membrane of plant cells.

Loosening of the Cell Wall Permits Plant Cell Growth

Because the cell wall surrounding a plant cell prevents it from expanding, the wall's structure must be loosened when the cell grows. The amount, type, and direction of plant-cell growth are regulated by small-molecule hormones called *auxins*. The auxin-induced weakening of the cell wall permits the expansion of the intracellular vacuole by uptake of water, leading to elongation of the cell. We can grasp the magnitude of this phenomenon by considering that, if all cells in a redwood tree were reduced to the size of a typical liver cell, the tree would have a maximum height of only 1 meter.

The cell wall undergoes its greatest changes at the **meristem** of a root or shoot tip. These sites are where cells divide and grow. Young meristematic cells are connected by thin primary cell walls, which can be loosened and stretched to allow subsequent cell elongation. After cell elongation ceases, the cell wall is generally thickened, either by the secretion of additional macromolecules into the primary wall or, more usually, by the formation of a secondary cell wall composed of several layers. Most of the cell eventually degenerates, leaving only the cell wall in mature tissues such as the xylem—the tubes that conduct salts and water from the roots through the stems to the leaves. The unique properties of wood and of plant fibers such as cotton are due to the molecular properties of the cell walls in the tissues of origin.

Plasmodesmata Directly Connect the Cytosols of Adjacent Cells in Higher Plants

The presence of a cell wall separating cells in plants imposes barriers to cell-cell communication—and thus cell-type differentiation—not faced by animals. One distinctive mechanism used by plant cells to communicate directly is through specialized cell-cell junctions called **plasmodesmata**, which extend

through the cell wall. Like gap junctions, plasmodesmata are channels that connect the cytosol of a cell with that of an adjacent cell. The diameter of the channel is about 30–60 nm, and its length can vary and be greater than 1 μm . The density of plasmodesmata varies depending on the plant and cell type, and even the smallest meristematic cells have more than 1000 interconnections with their neighbors. Although a variety of proteins and polysaccharides that are physically or functionally associated with plasmodesmata have been identified, key structural protein components of plasmodesmata and the detailed mechanisms underlying their biogenesis remain to be identified.

Molecules smaller than about 1000 Da, including a variety of metabolic and signaling compounds (ions, sugars, amino acids), generally can diffuse through plasmodesmata. However, the size of the channel through which molecules pass is highly regulated. In some circumstances, the channel is clamped shut; in others, it is dilated sufficiently to permit the passage of molecules larger than 10,000 Da. Among the factors that affect the permeability of plasmodesmata is the cytosolic Ca^{2+} concentration, with an increase in cytosolic Ca^{2+} reversibly inhibiting movement of molecules through these structures.

Although plasmodesmata and gap junctions resemble each other functionally with respect to forming channels for small-molecule diffusion, their structures differ dramatically in two significant ways (Figure 20-41). In plasmodesmata the plasma membranes of the adjacent plant cells merge to form a continuous channel, the *annulus*, whereas the membranes of cells at a gap junction are not continuous with each other. There are simple plasmodesmata (single pore) and complex plasmodesmata that branch into multiple channels. In addition, plasmodesmata exhibit many additional complex structural and functional characteristics. For example, they contain within the channel an extension of the endoplasmic reticulum called a *desmotubule* that passes through the annulus, which connects the cytosols of adjacent plant cells. They also have a variety of specialized proteins at the entrance of the channel and running throughout the length of the channel, including cytoskeletal, motor, and docking proteins that regulate the sizes and types of molecules that can pass through the channel. Many types of molecules spread from cell to cell through plasmodesmata, including some transcription-factor proteins, nucleic acid/protein complexes, metabolic products, and plant viruses. It appears that some of these require special chaperones to facilitate transport. Specialized kinases may also phosphorylate plasmodesmal components to regulate their activities (e.g., opening of the channels). Soluble molecules pass through the cytosolic annulus, about 3–4 nm in diameter, that lies between the plasma membrane and desmotubule, whereas membrane-bound molecules or certain proteins within the ER lumen can pass from cell to cell via the desmotubule. Plasmodesmata appear to play an especially important role in regulating the development of plant cells and tissues, as is suggested by their ability to mediate intracellular movement of transcription factors and ribonuclear protein complexes.

FIGURE 20-41 Plasmodesmata. (a) Schematic model of a plasmodesma showing the desmotubule, an extension of the endoplasmic reticulum (ER), and the annulus, a plasma-membrane-lined channel filled with cytosol that interconnects the cytosols of adjacent cells. (b) Electron micrographs of thin sections of a sugarcane leaf (brackets indicate individual plasmodesmata). (Left) Longitudinal view showing ER and desmotubule running through each annulus. (Right) Perpendicular cross-sectional views of plasmodesmata, in some of which spoke structures connecting the plasma membrane to the desmotubule can be seen. [Part (b) from K. Robinson-Beers and R. F. Evert, 1991, *Planta* **184**:307–318.]

Only a Few Adhesive Molecules Have Been Identified in Plants

Systematic analysis of the *Arabidopsis* genome and biochemical analysis of other plant species provide no evidence for the existence of plant homologs of most animal CAMs, adhesion receptors, and ECM components. This finding is not surprising, given the dramatically different nature of cell-cell and cell-matrix/cell-wall interactions in animals and plants.

Among the adhesive-type proteins apparently unique to plants are five wall-associated kinases (WAKs) and WAK-like proteins expressed in the plasma membrane of *Arabidopsis* cells. The extracellular regions in all these proteins contain

multiple epidermal growth factor (EGF) repeats, frequently found in animal cell-surface receptors, which may directly participate in binding to other molecules. Some WAKs have been shown to bind to glycine-rich proteins in the cell wall, thereby mediating membrane-wall contacts. These *Arabidopsis* proteins have a single transmembrane domain and an intracellular cytosolic tyrosine kinase domain, which may participate in signaling pathways somewhat like the receptor tyrosine kinases discussed in Chapter 16.

The results of in vitro binding assays combined with in vivo studies and analyses of plant mutants have identified several macromolecules in the ECM that are important for adhesion. For example, normal adhesion of pollen, which contains sperm cells, to the stigma or style in the female reproductive organ of the Easter lily requires a cysteine-rich protein called stigma/stylar cysteine-rich adhesin (SCA) and a specialized pectin that can bind to SCA (Figure 20-42). A small, probably ECM-embedded, ~10-kDa protein called chymocyanin works in conjunction with SCA to help direct the movement of the sperm-containing pollen tube (chemotaxis) to the ovary.

EXPERIMENTAL FIGURE 20-42 An in vitro assay was used to identify molecules required for adherence of pollen tubes to the stylar matrix. In this assay, extracellular stylar matrix collected from lily styles (SE) or an artificial matrix is dried onto nitrocellulose membranes (NC). Pollen tubes containing sperm are then added and their binding to the dried matrix is assessed. In this scanning electron micrograph, the tips of pollen tubes (arrows) can be seen binding to dried stylar matrix. This type of assay has shown that pollen adherence depends on stigma/stylar cysteine-rich adhesin (SCA) and a pectin that binds to SCA. [From G. Y. Jauh et al., 1997, *Sex Plant Reprod.* **10**:173.]

Disruption of the gene encoding glucuronyltransferase 1, a key enzyme in pectin biosynthesis, has provided a striking illustration of the importance of pectins in intercellular adhesion in plant meristems. Normally, specialized pectin molecules help hold the cells in meristems tightly together. When grown in culture as a cluster of relatively undifferentiated cells, called a callus, normal meristematic cells adhere tightly and can differentiate into chlorophyll-producing cells, giving the callus a green color. Eventually the callus will generate shoots. In contrast, mutant cells with an inactivated glucuronyltransferase 1 gene are large, associate loosely with each other, and do not differentiate normally, forming a yellow callus. The introduction of a normal glucuronyltransferase 1 gene into the mutant cells restores their ability to adhere and differentiate normally.

The paucity of plant adhesive molecules identified to date, in contrast with the many well-defined animal adhesive molecules, may be due to the technical difficulties in working with the ECM/cell wall of plants. Adhesive interactions are often likely to play different roles in plant and animal biology, at least in part because of their differences in development and physiology.

KEY CONCEPTS of Section 20.6

Plant Tissues

- The integration of cells into tissues in plants is fundamentally different from the assembly of animal tissues, primarily because each plant cell is surrounded by a relatively rigid cell wall.
- The plant cell wall comprises layers of cellulose microfibrils embedded within a matrix of hemicellulose, pectin, extensin, and other less abundant molecules.
- Cellulose, a large, linear glucose polymer, assembles spontaneously into microfibrils stabilized by hydrogen bonding.
- The cell wall defines the shapes of plant cells and restricts their elongation. Auxin-induced loosening of the cell wall permits elongation.
- Adjacent plant cells can communicate through plasmodesmata, junctions that allow molecules to pass through complex channels connecting the cytosols of adjacent cells (see Figure 20-41).
- Plants do not produce homologs of the common adhesive molecules found in animals. Only a few adhesive molecules unique to plants have been well documented to date.

Perspectives for the Future

A deeper understanding of the integration of cells into tissues in complex organisms will draw on insights and techniques from virtually all subdisciplines of molecular cell biology—biochemistry, biophysics, microscopy, genetics, genomics, proteomics, and developmental biology—together with bioengineering and computer science. This area of cell biology is undergoing explosive growth.

An important set of questions for the future deals with the mechanisms by which cells detect and respond to mechanical forces on them and the extracellular matrix, as well as the influence of their three-dimensional arrangements and interactions. A related question is how this information is used to control cell and tissue structure and function. These issues involve the fields of biomechanics and mechanotransduction. Shear or other stresses can induce distinct patterns of gene expression and cell growth and can greatly alter cell metabolism and responses to extracellular stimuli. Mechanosensitive nonselective cation channels (NSC_{MS}), at least some of which appear to be members of the transient receptor potential, or TRP, cation channel family, are activated by the stretch of plasma membrane. They are important players in mechanotransduction, such as that involved in sensing sound in the ear, which is mediated, in part, by specialized cadherins. Most of the classes of molecules discussed in this chapter—ECM components, adhesion receptors, CAMs, intracellular adapters, and the cytoskeleton—appear to play crucial roles in mechanosensing and mechanotransduction signaling pathways. Future research should give us a far more sophisticated understanding of the roles of the three-dimensional organization of cells and ECM components and the forces acting on them under normal and pathological conditions in controlling the structures and activities of tissues. Applications of such understanding will provide new methods to explore basic cell/tissue biology and provide improved technologies for the search for novel therapies for disease.

Although junctions help play a key role in forming stable epithelial tissues and defining the shapes and functional properties of epithelia, they are not static. Remodeling in terms of replacement of older molecules with more recently synthesized molecules is ongoing, and the dynamic properties of junctions open the door to more substantial changes when necessary (the epithelial-mesenchymal transition during development, wound healing, extravasation of leukocytes, etc.). Understanding the molecular mechanisms underlying the relationship between stability and dynamic change will provide new insights into morphogenesis, maintaining tissue integrity and function, and response to (or induction of) pathology.

Numerous questions relate to intracellular signaling from CAMs and adhesion receptors. Such signaling must be integrated with other cellular signaling pathways that are activated by various external signals (e.g., growth factors) so that the cell responds appropriately and in a coordinated fashion to many different simultaneous internal and external stimuli. It appears that small GTPase proteins participate in at least some of the integrated pathways associated with signaling between cellular junctions. How are the logic circuits constructed that allow cross talk between diverse signaling pathways? How do these circuits integrate the information from these pathways? How is the combination of outside-in and inside-out signaling mediated by CAMs and adhesion receptors merged into such circuits?

We can expect ever-increasing progress in the exploration of the influence of glycobiology (the biology of oligo- and polysaccharides) on cell biology. The importance of specialized GAG sequences in controlling cellular activities, especially

interactions between some growth factors and their receptors, is now clear. With the identification of the biosynthetic mechanisms by which these complex structures are generated and the development of tools to manipulate GAG structures and test their functions in cultured systems and intact animals, we can expect a dramatic increase in our understanding of the cell biology of GAGs in the next several years. There is still much to learn about the biosynthesis, structures, and functions of many other glycoconjugates, such as the O-linked sugars on dystroglycan that are essential for its binding to its ECM ligands. The new subspecialty field of *glycomics* has recently been flourishing and will contribute to our future understanding of glycobiology. Glycomics, similarly to genomics and proteomics, uses high-throughput tools, such as mass spectrometry, to perform large-scale analysis of the structures and changes in the wide range of sugar-containing molecules in cells and tissues.

A structural hallmark of CAMs, adhesion receptors, and ECM proteins is the presence of multiple domains that impart diverse functions to a single polypeptide chain. It is generally agreed that such multidomain proteins arose evolutionarily by the assembly of distinct DNA sequences encoding the distinct domains. Genes encoding multiple domains provide opportunities to generate enormous sequence and functional diversity by alternative splicing and the use of alternate promoters within a gene. Thus even though the number of independent genes in the human genome seems surprisingly small in comparison with other organisms, far more distinct protein molecules can be produced than predicted from the number of genes. Such diversity seems very well suited to the generation of proteins that take part in specifying adhesive connections in the nervous system, especially the brain. In fact, several groups of proteins expressed by neurons appear to have just such combinatorial diversity of structure. They include the protocadherins, a family of cadherins with many proteins encoded per gene (14–19 for the three genes in mammals); the neurexins, which comprise more than 1000 proteins encoded by three genes; and the Dscams, members of the IgCAM superfamily encoded by a *Drosophila* gene that has the potential to express 38,016 distinct proteins owing to alternative splicing. A continuing goal for future work will be to describe and understand the molecular basis of functional cell-cell and cell-matrix attachments—the “wiring”—in the nervous system and how that wiring ultimately permits complex neuronal control and, indeed, the intellect required to understand molecular cell biology.

Key Terms

adapter proteins 928	cell wall 968
adherens junction 934	collagen 946
adhesion receptor 927	connexin 943
anchoring junction 934	desmosome 935
basal lamina 933	elastin 951
cadherin 935	epithelial-mesenchymal
cell-adhesion molecule	transition 938
(CAM) 927	epithelia 926

extracellular matrix	laminin 947
(ECM) 927	matrix metalloproteases
fibrillar collagen 951	(MMPs) 960
fibronectin 957	multi-adhesive matrix
gap junction 934	protein 946
glycosaminoglycan	paracellular pathway 942
(GAG) 951	plasmodesmata 969
hyaluronan 956	proteoglycan 946
immunoglobulin	RGD sequence 939
cell-adhesion	selectin 965
molecule	syndecan 956
(IgCAM) 965	tight junction 934
integrin 939	

Review the Concepts

1. Describe the two phenomena that give rise to the diversity of adhesive molecules such as cadherins. What additional phenomenon gives rise to the diversity of integrins?
2. Cadherins are known to mediate homophilic interactions between cells. What is a homophilic interaction, and how can it be demonstrated experimentally for E-cadherins? What component of the extracellular environment is required for the homophilic interactions mediated by cadherins, and how can this requirement be demonstrated?
3. Together with their role in connecting the lateral membranes of adjacent epithelial cells, adherens junctions play a role in controlling cell shape. What associated intracellular structure and proteins are involved in this role?
4. What is the normal function of tight junctions? What can happen to tissues when tight junctions do not function properly?
5. Gap junctions between heart muscle cells and gap junctions between uterine myometrial smooth muscle cells form a connection that provides for rapid communication. What is this called? How is uterine myometrial smooth-muscle-cell gap-junction communication up-regulated for parturition (childbirth)?
6. What is collagen, and how is it synthesized? How do we know that collagen is required for tissue integrity?
7. Explain how changes in integrin structure mediate outside-in and inside-out signaling.
8. Compare the functions and properties of each of three types of macromolecules that are abundant in the extracellular matrix of all tissues.
9. Many proteoglycans have cell-signaling roles. Regulation of feeding behavior by syndecans in the hypothalamic region of the brain is one example. How is this regulation accomplished?
10. You have synthesized an oligopeptide containing an RGD sequence surrounded by other amino acids. What is the effect of this peptide when added to a fibroblast cell culture grown on a layer of fibronectin absorbed to the tissue culture dish? Why does this happen?

11. Describe the major activity and possible localization of the three major subgroups of proteins that remodel/degrade the ECM in physiological or pathological tissue remodeling. Identify a pathological condition in which these proteins play a key role.

12. Blood clotting is a crucial function for mammalian survival. How do the multi-adhesive properties of fibronectin lead to the recruitment of platelets to blood clots?

13. How do changes in molecular connections between the extracellular matrix (ECM) and cytoskeleton give rise to Duchenne muscular dystrophy?

14. To fight infection, leukocytes move rapidly from the blood into the tissue sites of infection. What is this process called? How are adhesion molecules involved in this process?

15. The structure of a plant cell wall needs to loosen to accommodate cell growth. What signaling molecule controls this process?

16. Compare plasmodesmata in plant cells to gap junctions in animal cells.

Analyze the Data

Researchers have isolated two E-cadherin mutant isoforms that are hypothesized to function differently from the iso-

form of the wild-type E-cadherin. An E-cadherin negative mammary carcinoma cell line was transfected with the mutant E-cadherin genes A (part a in the figure; triangles), or B (part b; triangles) or the wild-type E-cadherin gene (black circles) and compared to untransfected cells (open circles) in an aggregation assay. In this assay, cells are first dissociated by trypsin treatment and then allowed to aggregate in solution over a period of minutes. Aggregating cells from mutants A and B are presented in panels a and b respectively. To demonstrate that the observed adhesion was cadherin mediated, the cells were pretreated with a nonspecific antibody (left panel) or a function-blocking anti-E-cadherin monoclonal antibody (right panel).

a. Why do cells transfected with the wild-type E-cadherin gene have greater aggregation than control, untransfected cells?

b. From these data, what can be said about the function of mutants A and B?

c. Why does the addition of the anti-E-cadherin monoclonal antibody, but not the nonspecific antibody, block aggregation?

d. What would happen to the aggregation ability of the cells transfected with the wild-type E-cadherin gene if the assay were performed in media low in Ca^{2+} ?

Stem Cells, Cell Asymmetry, and Cell Death

Many descriptions of cell division imply that the parental cell gives rise to two daughter cells that look and behave exactly like the parental cell. In other words, they imply that cell division is **symmetric** and the progeny have properties similar to the parent cell. But if this were always the case, none of the hundreds of differentiated cell types and functioning tissues present in complex multicellular organisms would ever be formed. Differences among cells can arise when two initially identical daughter cells diverge on receiving distinct developmental or environmental signals. Alternatively, the two daughter cells may differ from “birth,” with each inheriting different parts of the parental cell (Figure 21-1). Daughter cells produced by such **asymmetric cell division** may differ in size, shape, and/or protein composition, or their genes may be in different states of activity or potential activity. The differences in these internal signals confer different fates on the two cells.

Striking examples of asymmetric cell division occur during early metazoan development, the focus of the first section of this chapter. The development of a new organism begins with the egg, or **oocyte**, carrying a set of chromosomes from

the mother, and the **sperm**, carrying a set of chromosomes from the father. These **gametes**, or sex cells, are haploid because they have gone through **meiosis** (see Chapter 19). In a process called **fertilization**, they combine to create the initial single cell, the **zygote**, which has two sets of chromosomes and is therefore **diploid**. During **embryogenesis**, the zygote undergoes numerous cell divisions, both symmetric and asymmetric, ultimately giving rise to an entire organism.

Such unspecialized cells that can reproduce themselves as well as generate specific types of more specialized cells are called **stem cells**. Their name comes from the image of a plant stem, which grows upward, continuing to form more stem, while also sending off leaves and branches to the side. In this chapter we will explore various types of stem cells that differ in the variety of specialized cell types they can form. The zygote is the ultimate **totipotent** stem cell because it has the capability to generate every cell type in the body as well as the supportive placental cells that are required for embryonic development.

As we will see later in the chapter, many of the early divisions of the nematode *C. elegans* are asymmetric, and each daughter cell gives rise to a discrete set of differentiated cell

21.3	Mechanisms of Cell Polarity and Asymmetric Cell Division	997
21.4	Cell Death and Its Regulation	1006

FIGURE 21-1 Overview of the birth, lineage, and death of cells.

Following growth, cells are “born” as the result of symmetric or asymmetric cell division. (a) The two daughter cells resulting from symmetric division are essentially identical to each other and to the parental cell. Such daughter cells subsequently can have different fates if they are exposed to different signals. The two daughter cells resulting from asymmetric division differ from birth and consequently have different fates. Asymmetric division commonly is preceded by the localization of regulatory molecules (green dots) in one part of the parent cell. (b) A series of symmetric and/or asymmetric cell divisions, called a cell lineage, gives birth to each of the specialized cell types found in a multicellular organism. The pattern of cell lineage can be under tight genetic control. Programmed cell death occurs during normal development (e.g., in the webbing that initially develops when fingers grow) and also in response to infection or toxins. A series of specific programmed events, called apoptosis, is activated in these situations.

types. In contrast, the mouse embryo passes through an eight-cell stage in which each cell can still form every tissue (both embryonic and extra-embryonic); that is, all eight cells are totipotent. At the 16-cell stage this is no longer true; some of the cells have become committed to particular differentiation paths. A group of cells called the inner cell mass (ICM) will ultimately give rise to all tissues of the embryo proper, and another set of cells will form the placental tissue. Cells such as those in the inner mass that can generate all embryonic tissues but not extra-embryonic tissues are called *pluripotent*. Cells of the ICM can be cultured in defined media, forming **embryonic stem (ES) cells**. ES cells can be grown indefinitely in culture, and each new cell remains pluripotent and can give rise to all of the tissues of an animal. We discuss the use of ES cells in uncovering the transcriptional network of gene expression underlying pluripotency and also the use of these cells in forming specific types of differentiated cells in culture for research purposes or, potentially, as “replacement parts” for outworn or diseased cells in patients.

For many years animal differentiation was thought to be unidirectional, but very recent data reveals that differentiation can be reversed experimentally; specialized, differentiated cells can be induced to revert back to an undifferentiated state. Strikingly, introducing just a small number of factors controlling the pluripotency of ES cells into multiple types of *somatic cells*, under defined conditions, can convert at least some of these somatic cells into **induced pluripotent stem (iPS) cells** that have properties seemingly indistinguishable from embryonic stem cells. As we will see in Section 21.1, iPS cells have profound utility for experimental biology and medicine.

The formation of working tissues and organs during development of multicellular organisms depends in part on specific patterns of mitotic cell division. A series of such cell divisions akin to a family tree is called a *cell lineage*. A cell lineage traces the birth order of cells as they progressively become more restricted in their developmental potential and *differentiate* into specialized cell types such as skin cells, neurons, or muscle cells (see Figure 21-1).

Many types of cells have lifetimes much less than that of the organism as a whole and so need to be constantly replaced. In mammals, for instance, cells lining the intestine and phagocytic macrophage cells live only a few days. Stem cells thus are important both during development and for replacement of outworn cells in adults. Unlike ES cells, the stem cells in the adult organism are *multipotent* stem cells: they can give rise to some types of differentiated cells found in the organism but not all of them. In the second section of this chapter we discuss several examples of multipotent stem cells, including those that give rise to germ cells, intestinal cells, and the variety of cell types found in blood.

We have already mentioned that the diversity of cells in an animal requires asymmetric cell division where the two daughter cells differ in fate. This process requires the mother cell to become asymmetric, or **polarized**, before cell division, so that cell contents are unequally distributed between the two daughters. This process of polarization is not only critical during development but also for the function of essentially all cells. For example, transporting epithelial cells, such as those that line the intestine, are polarized with their free apical surface facing the lumen to absorb nutrients and their basolateral surface contacting the extracellular matrix to transport nutrients toward the blood (see Figures 11-30 and 20-1). Other examples include cells migrating up a chemotactic gradient (see Figure 18-51) and neurons, with multiple dendrites extending from one side of the cell body that receive signals and a single axon extending from the other side that transmits signals to target cells (see Chapter 22). Thus the mechanisms that cells use to polarize are important and general aspects of their function. Not surprisingly, these mechanisms integrate elements of cell signaling pathways (see Chapters 15 and 16), cytoskeletal reorganization (see Chapters 17 and 18), and membrane trafficking (see Chapter 14). In the third section of this chapter we discuss how cells become polarized and how asymmetric cell division is critical for maintaining stem cells and their role in generating differentiated cells.

Typically we think of cell fates in terms of the differentiated cell types that are formed. A quite different cell fate, **programmed cell death**, also is absolutely crucial in the formation and maintenance of many tissues. A precise genetic regulatory system, with checks and balances, controls cell death just as other genetic programs control cell division and differentiation. In the last section of this chapter, we consider the mechanism of cell death and its regulation.

These aspects of cell biology—cell birth, the establishment of cell polarity, and programmed cell death—converge with developmental biology and are among the most important processes regulated by the signaling pathways discussed in earlier chapters.

21.1 Early Metazoan Development and Embryonic Stem Cells

The main focus of this section is on the first cell divisions that occur during early mammalian development and the properties of embryonic stem cells. We start with an explanation of how a single sperm is allowed to fuse with an egg, generating a zygote with a diploid genome from these two haploid germ cells.

Fertilization Unifies the Genome

It is remarkable that a mammalian sperm is ever able to reach and penetrate the egg. For one thing, in humans each sperm is competing with more than 100 million other sperm for a single oocyte. What's more, the sperm must swim an incredible distance to reach the egg (if a sperm was the size of a person, the distance traveled would be equivalent to several miles!). And once there, the sperm must fight its way through multiple layers surrounding the egg that restrict entry. The sperm is streamlined for speed and swimming ability, but only a few dozen will reach the oocyte. The human sperm flagellum (see Chapter 18) contains about 9000 dynein motors that flex microtubules in the 50- μm axoneme.

The acrosome, found at the sperm's leading tip, is a membrane-bound compartment specialized for interaction with the oocyte. The acrosome membrane is just under the plasma membrane at the sperm head; the other side of the acrosome membrane is juxtaposed to the nuclear membrane. Inside the acrosome are soluble enzymes, including hydrolases and proteases. In proximity to the oocyte, during fertilization, the acrosome undergoes exocytosis, releasing its contents onto the surface of the oocyte. Enzymes digest the multiple egg surface layers to begin the process of sperm entry. It's a race, and the first sperm to succeed triggers a dramatic response by the oocyte that prevents *polyspermy*, the entry of other sperm that would bring in excess chromosomes.

As shown in Figure 21-2, once it reaches the egg, a sperm must first penetrate a layer of cumulus cells that surround the oocyte and then the *zona pellucida*, a gelatinous extracellular matrix composed largely of three glycoproteins called ZP1,

ZP2, and ZP3. After the first sperm succeeds in fusing with the surface of the oocyte, a flux of calcium flows through the oocyte at about 5–10 $\mu\text{m/s}$, starting from the site of sperm entry. One of the effects of the calcium flux is to cause vesicles located just under the plasma membrane of the egg, the *cortical granules*, to release their contents to the outside of the plasma membrane and form a shielding fertilization membrane that blocks other sperm from entering. Finally the sperm nucleus enters the egg cytoplasm, and the egg and sperm nuclei soon fuse to create the diploid zygote nucleus.

Oocytes bring with them to the union a considerable dowry. They contain multiple circular mitochondrial DNAs whose inheritance is exclusively maternal; in mammals and many other species no sperm mitochondrial DNA enters the oocyte. Female-specific mitochondrial DNA inheritance has been used to trace maternal heritage in human history, for example following early humans from their origins in Africa. The egg cytoplasm is also packed with *maternal mRNA*: transcripts of genes essential for the earliest stages of development. There is little or no transcription during oocyte meiosis and the first embryo cleavages, so during this time the oocyte's RNA is crucial.

Cleavage of the Mammalian Embryo Leads to the First Differentiation Events

The fertilized egg, or zygote, does not remain a single cell for long. Fertilization is quickly followed by cleavage, a series of cell divisions that take about one day each (Figure 21-3); cleavage divisions happen before the embryo is implanted in the uterus wall. Initially the cells are fairly spherical and loosely attached to each other. As demonstrated experimentally in sheep, each cell at the eight-cell stage is totipotent and has the potential to give rise to a complete animal when implanted into the uterus of a pseudopregnant animal (one treated with hormones to make her uterus responsive to embryos).

Three days after fertilization the eight-cell embryo divides again to form the 16-cell *morula* (from the Greek for “raspberry”), after which the cell affinities increase substantially and the embryo undergoes *compaction*, a process that depends in part on the surface molecule E-cadherin (see Chapter 20). The compaction process is driven by increased cell-cell adhesion that initially results in a more solid mass of cells, the *compacted morula*. In the next step some of the cell-cell adhesions locally diminish, and fluid begins to flow into an internal cavity called the *blastocoel*. Additional divisions produce a **blastocyst** stage embryo, composed of approximately 64 cells, that has separated into two cell types: **trophoblast** (TE), which will form extra-embryonic tissues such as the placenta, and the **inner cell mass** (ICM) (just 10–15 cells in a mouse), which gives rise to the embryo proper (Figure 21-4a). In the blastocyst, the ICM is found on one side of the blastocoel, while the TE cells form a hollow ball around the ICM and blastocoel. At this point the TE cells are in an epithelial sheet, while the ICM cells are a loose mass that can be described as *mesenchymic*.

FIGURE 21-2 Gamete fusion during fertilization. (a) Mammalian eggs, such as the mouse oocyte shown here, are surrounded by a ring of translucent material, the zona pellucida, which provides a binding matrix for sperm. The diameter of a mouse egg is $\sim 70\ \mu\text{m}$, and the zona pellucida is $\sim 6\ \mu\text{m}$ thick. The polar body is a nonfunctional product of meiosis. Scale bar = $30\ \mu\text{m}$. (b) In the initial stage of fertilization, the sperm penetrates a layer of cumulus cells surrounding the egg **1** to reach the zona pellucida. Interactions between GalT, a protein on the sperm surface, and ZP3, a glycoprotein in the zona pellucida, trigger the acrosomal reaction **2**, which releases enzymes from the acrosomal vesicle. Degradation of the zona pellucida by hydrolases and proteases released during the acrosomal reaction allows the sperm to begin entering the egg **3**. Specific recognition proteins on the surfaces of egg and sperm facilitate fusion of their plasma membranes. Fusion and subsequent entry of the first sperm nucleus into the egg cytoplasm **4** and **5** trigger the release of Ca^{2+} within the oocyte. Cortical granules (orange) respond to the Ca^{2+} surge by fusing with the oocyte membrane and releasing enzymes that act on the zona pellucida to prevent binding of additional sperm. [Part (a) courtesy of Doug Kline; part (b) adapted from L. Wolpert et al., 2001, *Principles of Development*, 2nd ed., Oxford Press, Figure 12-22.]

FIGURE 21-3 Cleavage divisions in the mouse embryo. There is little cell growth during these divisions, so that the cells become

progressively smaller. See text for discussion. [Copyright Oxford University Press, T. Fleming.]

Mesenchyme, a term most commonly applied to mesoderm-derived cells, means loosely organized and loosely attached cells.

The fate of a cell in the early embryo—trophoblast or inner cell mass—is determined by the cell's location. If an experiment is done to place a labeled cell either on the outside or the inside of a very early embryo, cells on the outside tend to form extra-embryonic tissues while cells inserted inside tend to form embryonic tissues (Figure 21-4b, c). Gene expression measurements of each stage of early development show dramatic changes in which genes are expressed. Even these very early embryos use Wnt, Notch, and TGF β signals to regulate gene expression (see Chapter 16).

Both ICM and TE cells are stem cells: each starts its own distinct lineage and divides prolifically to produce diverse populations of cells. It is the ICM stem cells that we turn our attention to next.

The Inner Cell Mass Is the Source of Embryonic Stem (ES) Cells

Embryonic stem (ES) cells can be isolated from the inner cell mass (ICM) of early mammalian embryos and grown indefinitely in culture when attached to a feeder cell layer (Figure 21-5a). As mentioned in the chapter introduction, cultured ES cells are pluripotent: they can differentiate into a wide range of cell types of the three primary germ layers, either in vitro or after reinsertion into a host embryo. More specifically, mouse ES cells can be injected into the blastocoel cavity of an early mouse embryo and the cell aggregate surgically transplanted into the uterus of a pseudopregnant female. The ES cells will participate in forming most if not all tissues of the resultant chimeric mice (see Figure 5-41). The injected ES cells will often give rise to functional sperm and eggs that, in turn, can generate

EXPERIMENTAL FIGURE 21-4 Cell location determines cell fate in the early embryo. (a) A four-cell embryo normally develops into a blastocyst consisting of trophoblast (TE) cells on the outside and inner cell mass (ICM) cells inside. (b) In order to discover whether position affects the fates of cells, transplantation experiments were done with mouse embryos. First, recipient morula-stage embryos had cells removed to make room for implanted cells. Then donor morula-stage (16-cell) embryos were soaked in a dye that does not transfer between cells. Finally, labeled cells from the donor embryos were injected into inner or outer regions of the recipient embryos, as shown

in the micrograph. The recipient embryo is held in place by a slight vacuum applied to the holding pipette. (c) The subsequent fates of the descendants of the transplanted labeled cells were monitored. For simplicity, four-cell recipient cells are depicted, although morula-stage embryos were used as both donors and recipients. The results, summarized in the graphs, show that outer cells overwhelmingly form trophoblast and inner cells tend to become inner cell mass but also form considerable trophoblast. [Parts (a) and (c) adapted from L. Wolpert et al., 2001, *Principles of Development*, 2nd ed., Oxford Press, Figure 3-12; part (b) from R. L. Gardner and J. Nichols, 1991, *Human Reprod.* 6:25–35.]

EXPERIMENTAL FIGURE 21-5 Embryonic stem (ES) cells can be maintained in culture and can form differentiated cell types.

(a) Human or mouse blastocysts are grown from cleavage-stage embryos produced by in vitro fertilization. The inner cell mass is separated from the surrounding extra-embryonic tissues and plated onto a layer of fibroblast cells that help to nourish the embryonic cells by providing specific protein hormones. Individual cells are replated and form colonies of ES cells, which can be maintained for many generations and can be stored frozen. ES cells can also be cultured without a fibroblast feeder layer if specific cytokines are added; leukemia inhibitory factor (LIF), for instance, supports growth of mouse ES cells by triggering

Embryoid bodies

activation of the STAT3 transcription factor. (b) Embryonic stem cells allowed to differentiate in suspension culture become multicellular aggregates termed embryoid bodies (top). The bottom panels (c) are hematoxylin and eosin-stained sections of embryoid bodies that contain derivatives of all three germ layers that are formed from the inner cell mass during embryogenesis. Arrows in the images point to the following tissue types: (left) gut epithelium (endoderm), (middle) cartilage (mesoderm), and (right) neuroepithelial rosettes (ectoderm). Black bar = 100 μ m. [Part (a) adapted from J. S. Odorico et al., 2001, *Stem Cells* **19**:193–204; parts (b) and (c) courtesy Drs. Lauren Surface and Laurie Boyer.]

normal living mice. In more recent experiments the host blastocoel is treated with drugs that block mitosis so that the cells of the blastocyst become tetraploid (four copies of each chromosome), in contrast to the normal diploid ES cells that are injected into the blastocyst. In this case all of the cells in the living mice that are born after transplantation of the blastocyst aggregates derive from the donor ES cells. This is powerful evidence that single mouse ES cells indeed are pluripotent. Since these transplantation experiments cannot be done with human ES cells, formal proof that they are pluripotent is lacking.

Importantly, both human and mouse ES cells can differentiate into a wide range of cell types in culture. When placed in suspension culture, ES cells form multicellular ag-

gregates, called *embryoid bodies*, which resemble early embryos in the variety of tissues they form. When embryoid bodies are subsequently transferred to a solid surface, they grow into confluent cell sheets containing a variety of differentiated cell types, including gut epithelia, cartilage, and neural cells (Figure 21-5c). Under other conditions, ES cells have been induced to differentiate in culture into precursors for various cell types, including blood cells and pigmented epithelia; for this reason, ES cells have proved extremely useful in studies identifying the factors that commit a pluripotent cell to differentiating down a particular cell lineage.

What properties give these cells of the early embryo their remarkable plasticity? As we'll see in the next section, a

variety of actors play a role: DNA methylation, transcription factors, chromatin regulators, and micro-RNAs all affect which genes become active.

Multiple Factors Control the Pluripotency of ES Cells

During the earliest stages of embryogenesis, as the fertilized egg begins to divide, both the paternal and maternal DNA become demethylated (see the discussion of DNA methylation in Chapter 7). This happens in part because a key maintenance methyltransferase, Dnmt1, is transiently excluded from the nucleus and in part because of demethylase proteins that actively remove or “erase” these methylation marks during early development. As a result, the pattern of methylation is reset during the first few cell divisions, erasing earlier epigenetic marking of the DNA and creating a condition where cells have greater potential for diverse pathways of development. Mice engineered to lack Dnmt1 die as early embryos with drastically under-methylated DNA. ES cells prepared from such embryos are able to divide in culture, but in contrast to normal ES cells, cannot undergo in vitro differentiation.

ES cell properties are also critically dependent on the action of “master” transcription factors produced shortly after fertilization. The transcription factors Oct4, Sox2, and Nanog have essential roles in early development and are required for the specification of inner cell mass cells in the embryo as well as for specification of ES cells in culture. The expression of Oct4 and Nanog is exclusive to pluripotent cells such as the cells of the ICM and cultured ES cells. Sox2 is found in pluripotent cells, but its expression is also necessary in the multipotent neural stem cells that give rise exclusively to neuronal and glial cell types and that are discussed in the following section. Genetic studies in the mouse suggest that these regulators have distinct roles but may function in related pathways to maintain the developmental potential of pluripotent cells. For example, disruption of Oct4 or Sox2 results in the inappropriate differentiation of ICM and ES cells to trophectoderm, the cells that give rise to the placenta. However, forced expression of Oct4 in ES cells leads to a phenotype that is similar to loss of Nanog function. Thus, knowledge of the set of genes regulated by these transcription factors might reveal their essential roles during development.

The genes that are bound by these three transcription factors have been identified using chromatin immunoprecipitation experiments (see Chapter 7); each protein is found at more than a thousand chromosome locations. The target genes encode a wide variety of proteins, including the Oct4, Nanog, and Sox2 proteins themselves, forming an autoregulatory loop in which each of these transcription factors controls its own expression as well as that of the others (Figure 21-6). These transcription factors also bind to the promoter/enhancer regions of many genes encoding proteins and micro-RNAs important for the proliferation and self-renewal of ES cells.

Chromatin regulators that control gene transcription (see Chapter 7) are also important in ES cells. In *Drosophila*, Polycomb group proteins form complexes to maintain gene

FIGURE 21-6 Transcriptional network regulating pluripotency of ES cells. Each of the three “master” transcription factors, Oct4, Sox2, and Nanog, binds to its own promoter as well as the promoters of the other two (black lines), forming a positive autoregulatory loop that activates transcription of each of these genes. These transcription factors also bind to the promoter/enhancer regions of many active genes encoding proteins and micro-RNAs important for the proliferation and self-renewal of ES cells (magenta lines). These factors also bind to the promoter/enhancer regions of many genes that are silenced in undifferentiated ES cells and that encode proteins and micro-RNAs essential for formation of many differentiated cell types (magenta lines). [Adapted from L. A. Boyer et al., 2006, *Curr. Opin. Genetics Dev.* 16:455–462.]

repression states that have been previously established by DNA-binding transcription factors. Two mammalian protein complexes related to the fly Polycomb proteins, PRC1 and PRC2, are highly abundant in ES cells. Early mouse embryos lacking components of PRC2 display gastrulation defects, and ES cells lacking PRC2 functions cannot be maintained in an undifferentiated state. The PRC2 complex of proteins acts by adding methyl groups to lysine 27 of histone H3, thus altering chromatin structure to repress genes. (Note the methylation here is on an amino acid in a protein, a type of regulation distinct from the methylation of DNA.) In ES cells, PRC1 and PRC2 both silence genes whose encoded proteins or micro-RNAs (miRNAs) would otherwise induce differentiation into particular types of differentiated cells; the Polycomb proteins also maintain these genes in an epigenetic “preactivation” state such that they are poised to become activated later as part of the proper execution of specific developmental gene expression programs.

Many other regulators play important roles in controlling gene expression and maintaining pluripotency during very early development. For example, the gene encoding the miRNA let-7 is transcribed in ES cells, but the precursor RNA transcript is not cleaved to form the mature, functional miRNA. ES cells express a developmentally regulated RNA binding protein termed Lin28 that binds to the let-7 precursor RNA and prevents its cleavage. Experimental expression of mature let-7 miRNA in ES cells blocks their ability to undergo self-renewal, and thus repression of let-7 processing by Lin28 is essential for pluripotency.

 The possibility of using embryonic stem cells therapeutically to restore or replace damaged tissue is fueling much research on how to induce them to differentiate into

specific cell types. For example, if neurons that produce the neurotransmitter dopamine could be generated from stem cells grown in culture, it might be possible to treat people with Parkinson's disease who have lost such neurons.

By treating ES cells successively with sets of hormones, it is possible to generate cells that produce insulin. However, these cells produce only a fraction of the insulin made by a beta pancreatic islet cell, and they do not secrete insulin normally in response to changes in glucose concentration in the medium (see discussion in Chapter 16). Recently, human ES cells were triggered to differentiate into a type of islet progenitor cell termed *pancreatic endoderm*; when these cells were transplanted into mice, they generated functional beta cells that correctly processed human proinsulin into insulin (see Figure 14-24) and secreted human insulin normally in response to elevations in blood glucose. Much work is dedicated to coaxing these ES-derived endoderm cells to become normal beta cells in culture that can be used to treat human diabetic patients. However, many important questions must be answered before the feasibility of using human embryonic stem cells for therapeutic purposes can be assessed adequately. For instance, when undifferentiated ES cells are transplanted into an experimental animal, they form teratomas, a tumor that contains masses of partially differentiated cell types; thus it is essential to ensure that *all* of the ES cells used to generate an implant have indeed undergone differentiation and have lost their pluripotency. ■

Apart from their possible benefit in treating disease, ES cells have already proved invaluable for producing mouse mutants useful in studying a wide range of diseases, developmental mechanisms, behavior, and physiology. Using recombinant DNA techniques described in Chapter 5, one can eliminate or modify the function of a specific gene in ES cells (see Figure 5-40). The mutated ES cells then can be employed to produce mice with a gene knockout (see Figure 5-41). Analysis of the effects caused by deleting or modifying a gene in this way often provides clues about the normal function of the gene and its encoded protein.

Animal Cloning Shows That Differentiation Can Be Reversed

Although different cell types may transcribe different parts of the genome, for the most part the genome is identical in all cells. Segments of the genome are rearranged and lost during development of T and B lymphocytes from hematopoietic precursors (see Chapter 23), but most somatic cells appear to have an intact genome, equivalent to that in the germ line. Evidence that at least some somatic cells have a complete and functional genome comes from the successful production of cloned animals by nuclear-transfer. In this procedure, often called somatic-cell nuclear transfer (SCNT), the nucleus of an adult somatic cell is introduced into an egg where the nucleus has been removed; the manipulated egg, which contains the diploid number of chromosomes and is equivalent to a zygote, is then implanted into a foster mother. The only source of

genetic information to guide development of the embryo is the nuclear genome of the donor somatic cell. The low efficiency of generating cloned animals by SCNT, combined with a high frequency of diseases such as obesity in the animals that are cloned, however, raises questions about how many adult somatic cells do in fact have a complete functional genome and whether those that do can be completely reprogrammed into a pluripotent undifferentiated state. Even the successes, such as the famous cloned sheep "Dolly," have some medical problems. Even if differentiated cells have a physically complete genome, clearly only parts of it are transcriptionally active (see Chapter 7). A cell could, for example, have an intact genome but be unable to properly reactivate specific genes due to inherited chromatin epigenetic states.

Further evidence that the genome of a differentiated cell can revert to having the full developmental potential characteristic of an embryonic stem cell comes from experiments where postmitotic olfactory sensory neurons were genetically marked with green fluorescence protein (GFP) and then used as donors of nuclei (Figure 21-7). When the nuclei from differentiated olfactory cells were implanted into enucleated mouse oocytes, a small fraction of them developed into blastocysts that produced GFP. The blastocysts were used to derive ES cell lines, which were then used to generate mouse embryos. These embryos, derived entirely from olfactory neuron genomes, formed healthy green-fluorescing mice. Thus, at least in some cases, the genome of a differentiated cell can be reprogrammed completely to form all tissues of a mouse.

Somatic Cells Can Generate Induced Pluripotent Stem (iPS) Cells

Because of the inefficiency of somatic nuclear transfer, it remained unclear whether all types of somatic mammalian cells retained an intact genome and whether they could be induced to dedifferentiate into an ES-cell-like state. Shinya Yamanaka used retrovirus vectors to express a wide variety of transcription factors, singly and in combination, in cultured mouse fibroblasts. Remarkably, he found that both human and mouse cells could be reprogrammed to a pluripotent state, called an **induced pluripotent stem cell (iPS)** state, similar to that of an embryonic stem cell, following transduction with retroviruses encoding just four factors: KLF4, SOX2, OCT4, and c-MYC. Note that two of these, Sox2 and Oct4, are two of the master transcriptional regulators in ES cells discussed previously. Expression of combinations of these and other transcription factors induces iPS formation from many types of somatic cells, including antibody-producing B cells.

It was hypothesized that over time, forced expression of these genes activates expression of many cellular genes, including those encoding the Oct4, Nanog, and Sox2 pluripotency proteins that, over the course of several weeks, reprogram the somatic cells to an ES-like state. To experimentally establish this point, synthetic messenger RNAs encoding the four canonical Yamanaka transcription factors, KLF4, SOX2, OCT4, and c-MYC, were repeatedly transfected into cultured keratinocyte (skin-forming) cells. These

EXPERIMENTAL FIGURE 21-7 Mice can be cloned by somatic-cell nuclear transplantation from olfactory neurons. (a) Strategy to generate cloned ES cell lines using nuclei from olfactory sensory neurons and generation of cloned mice. **1** A nucleus from an olfactory sensory neuron isolated from a mouse that expresses green fluorescent protein (GFP) only in olfactory neurons was used to replace the nucleus of a mouse egg, and the resultant zygote was differentiated in culture until the inner cell mass stage. **2** The inner mass cells, all of which were clones of the original olfactory sensory neuron, and all of which expressed GFP, were used to generate lines of ES cells **3**, and **4** these

ES cells were injected into a tetraploid blastocyst. **5** When the blastocyst was transplanted into the uterus of a pseudopregnant mouse, the tetraploid cells from the host blastocyst could form the placenta (gray) but not the embryo proper, and **6** all of cells in the embryo proper and in the mice that were born expressed GFP. (b) Bright-field (top) and fluorescence images (bottom) of nuclear transfer blastocysts and (c) the ES cells that were isolated from the inner cell mass cells. (d) A control 12-h-old mouse (top) and a mouse cloned from an olfactory sensory neuron (bottom), all of whose cells expressed GFP. [From K. Eggan et al., 2004, *Nature* **428**:44.]

cultured cells generated normal iPS cells that had no trace of any of the exogenously added messenger RNAs, attesting to the reprogramming of keratinocytes into iPS cells by inducing expression only of normal cellular genes.

As with ES cells, single iPS cells can be experimentally introduced into a blastocyst and form all of the tissues of a mouse, including germ cells, attesting to the fact that somatic cells indeed can be reprogrammed into an embryonic state.

 Because iPS cells can be derived from somatic cells of patients with difficult-to-understand diseases, they have already proved invaluable in uncovering the cellular basis of several afflictions. Consider amyotrophic lateral sclerosis (ALS), a fatal disease characterized by the degeneration of somatic motor neurons in the spinal cord, brain stem, and brain cortex. In approximately 10 percent of patients the disease is dominantly inherited (familial ALS), but in 90 percent of patients there is no apparent genetic linkage (sporadic ALS). In about 20 percent of familial ALS patients there is a point mutation in the gene encoding Cu/Zn superoxide dismutase 1 (SOD1). There is some evidence that the

mutant SOD1 protein forms aggregates that can damage cells, but whether the mutant form of SOD1 causes damage directly to the motor neurons or to the surrounding glial cells (see Figure 22-14) was not known.

In one revealing study iPS cells were derived from elderly patients with the familial form of the disease and successfully differentiated in culture to motor neurons as well as glial cells. This demonstrated the feasibility of leveraging the self-renewal of iPS cells to generate a potentially limitless supply of the cells specifically affected by ALS. In a separate study to dissect the molecular cause of ALS, motor neurons were generated from human ES or iPS cells and cultured with primary human astrocytes (a type of glial cell). About half of the motor neurons died if the glial cells expressed the mutant form of SOD1, suggesting that at least in the familial form of ALS, the defective cells are the astrocytes. Indeed, astrocytes expressing the mutant form of SOD1 secreted protein factors that were toxic to adjacent motor neurons. Determining the nature of these factors could lead to a therapy for ALS, but in any case, these experiments illustrate the value of iPS and ES cells in generating cell culture models of

human disease that could be used to screen for drugs that could treat the affliction. ■

KEY CONCEPTS of Section 21.1

Early Metazoan Development and Embryonic Stem Cells

- In asymmetric cell division, two different types of daughter cells are formed from one mother cell. In contrast, both daughter cells formed in symmetric divisions are identical but may have different fates if they are exposed to different external signals (see Figure 21-1).
- Specialized sperm and egg surface proteins allow the nucleus of a single mammalian sperm to enter the cytoplasm of an egg. Fusion of a haploid sperm and haploid egg nucleus generates a diploid zygote.
- Initial divisions of the mammalian embryo yield equivalent totipotent cells, but subsequent divisions yield the first differentiation event, the separation of the trophoblast epithelium from the inner cell mass.
- The inner cell mass is the source of the embryo proper as well as of embryonic stem (ES) cells.
- Cultured embryonic stem cells (ES cells) are pluripotent, capable of giving rise to all differentiated cell types of the organism with the exception of extra-embryonic tissues. They are useful in production of genetically altered mice and offer potential for therapeutic uses.
- The pluripotency of ES cells is controlled by multiple factors, including the state of DNA methylation, chromatin regulators, certain micro-RNAs, and the transcription factors Oct4, Sox2, and Nanog.
- Animal cloning establishes that cell differentiation can be reversed.
- Induced pluripotent stem (iPS) cells can be formed from somatic cells by expression of combinations of key transcription factors, including KLF4, SOX2, OCT4, and c-MYC.

21.2 Stem Cells and Niches in Multicellular Organisms

Many differentiated cell types are sloughed from the body or have life spans that are shorter than that of the organism. Disease and trauma also can lead to loss of differentiated cells. Since most types of differentiated cells generally do not divide, they must be replenished from nearby stem-cell populations. Postnatal (adult) animals contain stem cells for many tissues, including the blood, intestine, skin, ovaries and testes, and muscle. Even some parts of the adult brain, where little cell division normally occurs, have a population of stem cells. In muscle, stem cells are most important in healing, as relatively little cell division occurs at other times. Some other cell types, such as liver cells (hepatocytes) and insulin-producing beta pancreatic islet cells, mainly reproduce by division of already differentiated cells, as exempli-

fied by regeneration of the liver when large pieces are surgically removed. It is controversial whether these tissues also contain stem cells that can generate these types of differentiated cells.

Stem Cells Give Rise to Both Stem Cells and Differentiating Cells

Stem cells, which give rise to the specialized cells composing body tissues, have three key properties:

- They can give rise to multiple types of differentiated cells; they are *multipotent*. In this sense they are different from *progenitor cells*, which generally give rise to only a single type of differentiated cell. A stem cell has the capability of generating a number of different cell types but not all; that is, it is not pluripotent like an ES cell. For instance, a multipotent blood stem cell will form more of itself plus multiple types of blood cells but never a skin or a liver cell.
- Stem cells are undifferentiated; in general, they do not express proteins characteristic of the differentiated cell types formed by their descendants.
- The number of stem cells of a particular type generally remains constant over an individual's lifetime. In that sense stem cells are often said to be immortal, although no single stem cell survives for the life of the animal.

Stem cells can exhibit several patterns of cell division, outlined in Figure 21-8. A stem cell may divide symmetrically to yield two daughter stem cells identical to itself. Alternatively, a stem cell may divide asymmetrically to generate one copy of itself and one daughter stem cell that has more restricted capabilities, such as dividing for a limited time or giving rise to fewer types of progeny compared with the parental stem cell. For example, each time a stem cell in the intestine divides, one of the daughters becomes a stem cell identical to its parent while the other daughter cell divides rapidly and generates four types of differentiated intestinal cells, as we will see in greater detail shortly.

The two critical properties of stem cells that together distinguish them from all other cells are the ability to reproduce themselves indefinitely, often called *self-renewal*, and the ability to, as needed, divide asymmetrically to form one daughter stem cell identical to itself and one daughter cell of more restricted potential. Many stem-cell divisions are symmetric, producing two stem cells, but at some point some progeny need to differentiate. In this way, mitotic division of stem cells can either enlarge the population of stem cells or maintain a stem-cell population while steadily producing a stream of differentiating cells. Although some types of progenitor cells can divide symmetrically to form more of themselves, they do so only for limited periods.

Stem Cells for Different Tissues Occupy Sustaining Niches

Stem cells need the right microenvironment. In addition to *intrinsic* regulatory signals—such as the presence of certain regulatory proteins—stem cells rely on *extrinsic* hormonal and other regulatory signals from surrounding cells to maintain

FIGURE 21-8 Patterns of stem-cell differentiation. Alternate patterns of stem-cell division produce more stem cells (blue) and differentiating cells (green). Stem-cell divisions meet three objectives: they must maintain the stem-cell population, sometimes they must increase the number of stem cells, and at the right time they must produce cells that go on to differentiate. (a) Stem cells can undergo asymmetric divisions, producing one stem cell and one differentiating cell. This does not increase the population of stem cells. (b) Some stem cells can divide symmetrically to increase their population, which may be useful in normal development or during recovery from injury, at the same time that others are dividing asymmetrically as in (a). (c) Cells may divide as in (b) while at the same time some stem cells produce two differentiating progeny. [From S. J. Morrison and J. Kimble, 2006, *Nature* 441:1068–1074.]

their status as stem cells. The location where a stem-cell fate can be maintained is called a **stem-cell niche**, by analogy to an ecological niche—a location that supports the existence and competitive advantage of a particular organism. The right combination of intrinsic and extrinsic regulation, imparted by a niche, will create and sustain a population of stem cells.

In order to investigate or use stem cells, they must be found and characterized. It is often difficult to identify stem cells precisely; they are very rare and generally lack distinctive shapes and do not even divide particularly rapidly. Stem cells can be held in reserve, dividing slowly if at all, until stimulated by signals that convey the need for new cells. For example, inadequate oxygen supplies can stimulate blood stem cells to divide, and injury to the skin can stimulate regenerative cell division starting with the activation of stem cells. Some stem cells, including those that form the continuously shed epithelium of the intestine, are continuously dividing, usually at a slow rate.

Germ-Line Stem Cells Produce Sperm and Oocytes

The *germ line* is the cell lineage that produces oocytes and sperm. It is distinct from the somatic cells that make all the other tissues but are not passed on to progeny. The germ line, like somatic-cell lineages, starts with stem cells. Stem-cell niches have been especially well defined in studies of germ-line stem cells (GSCs) in *Drosophila* and *C. elegans*. Germ-line stem cells are present in adult flies and worms, and the location of the stem cells is well known.

In the fly ovary, the niche where oocyte precursors form and begin to differentiate is located next to the tip of the *germarium* (Figure 21-9a). There are two or three germ-line stem

FIGURE 21-9 A *Drosophila* germarium. (a) Cross section of the germarium showing female germ-line stem cells (yellow) and some somatic stem cells (gold) in their niches and the progeny cells derived from them. The germ-line stem cells produce cystoblasts (green), which undergo four rounds of mitotic division to produce 16 interconnected cells, one of which becomes the oocyte; the somatic stem cells produce follicle cells (brown) that will make the eggshell. The cap cells (dark green) create and maintain the niche for germ-line stem cells, while the inner sheath cells (blue) produce the niche for somatic stem cells. (b) Signaling pathways that control the properties of germ-line stem cells. The signaling molecules—the TGF- β family proteins Dpp and Gbb as well as Hedgehog (Hh)—are produced by cap cells. Binding of these ligands to receptors on the surface of a germ-line stem cell, the TGF- β receptors I and II, and Ptc, respectively, results in repression of the *bam* gene by two transcription factors, Mad and Med and a co-repressor *Schnurri*. Repression of *bam* allows germ-line stem cells to renew, whereas activation of *bam* promotes differentiation. The transmembrane cell-adhesion protein E-cadherin forms the homotypic adherens junctions between germ-line stem cells and cap cells. Arm (armadillo) is the fly β -catenin and connects the cytoplasmic tails of the E-cadherin to the actin cytoskeleton; both E-cadherin and Arm are important in maintaining the stem-cell niche. (c) Signaling pathways that control the properties of somatic stem cells. The Wnt signal Wingless (Wg) is produced by the inner sheath cells and is received by the Frizzled receptor (Fz) on a somatic stem cell. Hh is similarly produced and is received by the Ptc receptor. Both receptors signal to control transcription that results in self-renewal of somatic stem cells. [Adapted from L. Li and T. Xie, 2005, *Ann. Rev. Cell Devel. Biol.* 21:605.]

cells in this location next to a few cap cells, which create the niche by secreting two **transforming growth factor beta** (TGF- β) family proteins (Dpp and Gbb) and **Hedgehog** (Hh) protein (Figure 21-9b). These secreted protein signals were introduced in Chapter 16. Cap cells create the niche because the TGF- β class signals they send repress transcription of a key differentiation factor, the *Bag of marbles* (*Bam*) protein, in the neighboring germ-line stem cells. The stem cells are held in the niche by the transmembrane cell-surface protein E-cadherin, which makes adherens junctions via homotypic interactions with similar E-cadherin molecules on the cap cell. *Armadillo* (*Arm*), the fly β -catenin, connects the cytoplasmic tails of the E-cadherin to the actin cytoskeleton; like E-cadherin, *Arm* is important in maintaining the stem-cell niche.

When a germ-line stem cell divides, one of the resulting two daughters remains adjacent to the cap cells and is therefore maintained as a stem cell, like the mother cell. The other daughter is displaced away and becomes a cystoblast, which is too far from the cap cells to receive the cap-cell-derived signals Dpp and Gbb. As a result, *Bam* expression turns on, causing the germ cell to enter the differentiation program.

Separate somatic stem cells in the gerarium produce follicle cells that will make the eggshell. The somatic stem cells have a niche too, created by the inner sheath cells, which produce Wingless (Wg) protein—a fly **Wnt** signal—and Hh protein (Figure 21-9c). Hedgehog produced by the cap cells may also play a role. Thus two different populations of stem cells can work in close coordination to produce different parts of an egg.

In worms, the long tubelike arms of the gonads have tips where a single cell called a distal tip cell creates a stem cell niche (Figure 21-10). The transmembrane protein Delta, produced by the distal tip cell, binds to the Notch receptor on the adjacent germ-line stem cells. The Delta/Notch signaling pathway (see Figure 16-35) in worm germ-line stem cells both represses the induction of differentiation-promoting gene products that drive entry into meiosis (i.e., germ-line differentiation) and promotes symmetric self-renewing mitotic division that creates more daughter stem cells. Meiosis is thus blocked by the Delta signal until the stem cells move beyond the range of the signal from the distal tip cell. Mutations that activate Notch in the germ-line stem cells, even in the absence of Delta signal, cause a gonadal tumor with massive numbers of extra germ-line stem cells, due to excessive mitosis and little meiosis.

The identification and characterization of *Drosophila* and *C. elegans* germ-line stem cells were important because they showed convincingly the existence of stem-cell niches and permitted experiments to identify the niche-made signals that cause cells to become and remain self-renewing stem cells. Thus a stem-cell niche is a set of cells and the signals they produce, not just a location.

Identification of specific molecules that maintain the stem-cell state in *Drosophila* and *C. elegans* brought an unexpected bonus: Some of these molecules are also used to form stem-cell niches and control stem-cell fates in mammals. For example, germ-line stem cells in the mouse testis are dependent

FIGURE 21-10 Germ-line stem cells in *C. elegans*. A cross section of the tip of the gonad shows stem cells in their niche and progeny derived from them. The single distal tip cell (green) creates and maintains the niche; it expresses Delta on its surface, which binds to the Notch receptor on the adjacent germ-line stem cells. The signals induced in these stem cells promote symmetric, self-renewing mitosis that forms two daughter germ-line stem cells. As these stem cells move outward beyond the range of the Delta signal, they continue to divide but are able to self-renew for no more than a few divisions. Eventually they become meiotic progenitor cells that form the germ cells. During these stages the cells are only partially separated by membranes ("Y" shapes) and therefore are a syncytium. [Adapted from L. Li and T. Xie, 2005, *Annu. Rev. Cell Dev. Biol.* 21:605–631.]

on a TGF- β family signaling protein (GDNF) derived from somatic cells. Each seminiferous tubule contains a small number of germ-line stem cells that divide asymmetrically to recreate themselves and to produce spermatogonial cells. Spermatogonia proliferate and their progeny become spermatocytes, which go through the extraordinary differentiation process that builds a sperm. The niche is created by a specialized region of a Sertoli cell along with a myoid cell and a basement membrane produced by the myoid cell, though many details of the molecular signals remain to be explored.

Intestinal Stem Cells Continuously Generate All of the Cells of the Intestinal Epithelium

The epithelium lining the small intestine is a single cell thick (see Figure 20-10) and is composed of three types of differentiated cells. The most abundant epithelial cells, the absorptive enterocytes, transport nutrients essential for survival from the intestinal lumen into the body (see Figure 11-30). The intestinal epithelium is the most rapidly self-renewing tissue in adult mammals, turning over every five days. The cells of the intestinal epithelium continuously regenerate from a stem-cell population located deep in the intestinal wall in pits called *crypts* (Figure 21-11). Pulse-chase experiments showed that intestinal stem cells produce precursor

FIGURE 21-11 Intestinal stem cells. Schematic drawing of an intestinal crypt showing the intestinal stem cells (yellow), their mitotic progeny (light green), and the site of terminal differentiation (dark green). The base of the crypt is the location of Paneth cells (orange), which provide a major part of the stem-cell niche and also secrete anti-microbial defense proteins called defensins that form pores in bacterial membranes, killing bacteria. Mesenchymal cells (blue) surround the base of the crypt and also secrete proteins such as Wnt that promote stem-cell fates, offsetting BMP signals that push toward differentiation. [Adapted from L. Li and T. Xie, 2005, Stem cell niche: structure and function, *Annu. Rev. Cell Dev. Biol.* **21**:605–631, and T. Sato et al., 2011, *Nature* **469**:415.]

cells that proliferate and then differentiate as they ascend the sides of crypts to form the surface layer of the fingerlike gut projections called *villi*, across which intestinal absorption occurs. The time from cell birth in the crypts to the loss of cells at the tip of the villi is only about 3 to 4 days (Figure 21-12). Thus enormous numbers of cells must be produced continually to keep the epithelium intact. The production of new cells is precisely controlled: too little division would eliminate villi and lead to breakdown of the intestinal surface; too much division would create an excessively large epithelium and also might be a step toward cancer.

Experiments such as the one depicted in Figure 21-12 suggested that the intestinal stem cells were located somewhere near the bottom of the crypts, near differentiated intestinal cells called Paneth cells. But these putative stem cells have no particular morphological characteristics that reveal their remarkable abilities; which cells are the actual intestinal stem cells and which are the supportive cells that form the niche?

Prior genetic experiments had shown that Wnt signals were essential for intestinal stem cell maintenance. As evidence for the importance of Wnts, overproduction of active β -catenin (normally activated by Wnt signals; see Figure 16-30) in intestinal cells leads to excess proliferation of the intestinal epi-

thelium. Conversely, blocking the function of β -catenin by interfering with the Wnt-activated TCF transcription factor abolishes the stem cells in the intestine. Thus Wnt signaling plays a critical role in the intestinal stem cell niche as it does in the skin and other organs. Indeed, mutations that inappropriately activate Wnt signal transduction are a major contributor to the progression of colon cancer, as we will see in Chapter 24.

By analyzing a panel of genes whose expression in the intestine was induced by Wnt signaling, investigators zeroed in on *Lgr5*, encoding a G protein-coupled receptor, because it was expressed only in a small set of cells at the very base of the crypts. *Lgr5* binds a class of secreted hormones termed R-spondins and activates intracellular signaling pathways that potentiate Wnt signaling. Lineage-tracing studies showed

EXPERIMENTAL FIGURE 21-12 Regeneration of the intestinal epithelium from stem cells can be demonstrated in pulse-chase experiments. Results from a pulse-chase experiment in which radioactively labeled thymidine (the pulse) was added to a tissue culture of the intestinal epithelium. Dividing cells incorporated the labeled thymidine into their newly synthesized DNA. The labeled thymidine was washed away and replaced with nonlabeled thymidine (the chase) after a brief period; cells that divided after the chase did not become labeled. These micrographs show that 40 minutes after labeling, the entire label is in cells near the base of the crypt. At later times, the labeled cells are seen progressively farther away from their point of birth in the crypt. Cells at the top are shed. This process ensures constant replenishment of the gut epithelium with new cells. [Courtesy of C. S. Potten; from P. Kaur and C. S. Potten, 1986, *Cell Tiss. Kinet.* **19**:601.]

EXPERIMENTAL FIGURE 21-13 Lineage-tracing studies show that the $Lgr5^+$ cells at the base of crypts are the intestinal stem cells.

(a) Outline of the experiment. Using genetically altered ES cells (see Figure 5-40), investigators generated one strain of mice in which a version of the Cre recombinase (see Figure 5-42) was placed under control of the *Lgr5* promoter, and thus the Cre recombinase was produced only in cells, such as intestinal stem cells, that express the *Lgr5* gene. This version of the Cre recombinase contained an additional domain from the estrogen receptor (ER) that binds the estrogen analog tamoxifen; like the estrogen receptor and other nuclear receptors such as the glucocorticoid receptor (Figure 7-44), the ER-Cre chimera was retained in the cytosol unless tamoxifen was added. In the presence of tamoxifen, ER-Cre moves into the nucleus, where it can interact with *loxP* sites in the chromosomal DNA. The second reporter strain of mice contained a bacterial β -galactosidase gene that was preceded by two *loxP* sites. The blocking segment of DNA in between these *loxP* sites prevented expression of the β -galactosidase gene, and the β -galactosidase gene could only be expressed in cells where an active Cre recombinase had removed the sequence in between the two *loxP* sites. The two mice were mated, and offspring containing both marker transgenes were identified. In these mice β -galactosidase was expressed only in cells in which the *Lgr5*-controlled ER-Cre gene was expressed and only after addition of the estrogen analog tamoxifen to the mice. Thus only *Lgr5*-expressing cells—and all of their descendants—would express the β -galactosidase gene. (b) Results of the experiment. One day after adding tamoxifen to these mice, the only cells expressing β -galactosidase (measured by the blue histochemical stain) were the *Lgr*-expressing intestinal stem cells at the base of the crypts (left). Five days after tamoxifen, additional blue cells—the epithelial descendants of the intestinal stem cells—were seen migrating up the sides of the villi. Some blue stem cells remained at the bottom of the crypt. [Part (b) from N. Barker et al., 2007, *Nature* 449:1003.]

that the descendants of these *Lgr*-expressing cells indeed gave rise to all of the intestinal epithelial cells (Figure 21-13). This experiment made use of gene-altered mice in which a version of the Cre recombinase (see Figure 5-42), an estrogen receptor (ER)-Cre chimera, was placed under control of the *Lgr* promoter; thus the ER-Cre chimera recombinase was produced only in the few putative *Lgr5*-expressing stem cells at the bottom of the crypts. The version of the Cre used in the study had been altered so that normally it resides inactive in the cytosol and is transferred into the nucleus only after addition of an estrogen analog (Figure 21-13a). There the Cre excises a segment of DNA, activating expression of a β -galactosidase reporter gene in these cells. Importantly, all of the descendants of these cells will also express this enzyme. Immediately after addition of the estrogen analog, the only cells expressing β -galactosidase are the stem cells in the crypts. But after a few days all of the descendant epithelial cells also expressed β -galactosidase (Figure 21-13b), showing that *Lgr5* indeed is a marker of the intestinal stem cells.

In subsequent studies, single *Lgr5*-expressing stem cells were isolated from intestinal crypts and cultured on an extracellular matrix (see Figure 20-22) containing type IV collagen and laminin that normally underlies and supports the intestinal epithelia. These cells generated villus-like structures that

contained all four differentiated cell types found in the mature intestinal epithelium (Figure 21-14). Taken together, these experiments establish that expression of the *Lgr5* gene defines the intestinal stem cells and shows that these cells are localized at the base of the intestinal crypts interspersed between the terminally differentiated Paneth cells (see Figure 21-11).

Paneth cells produce several antibacterial proteins that protect the intestine from infections; surprising recent evidence suggests that Paneth cells also constitute a major part of the niche for the intestinal stem cells. Cultured Paneth cells produce Wnt as well as other hormones, such as EGF and a

EXPERIMENTAL FIGURE 21-14 Single *Lgr5*-expressing intestinal stem cells build crypt-villus structures in culture without niche cells. Single *Lgr5*-expressing cells isolated from intestinal crypts were placed in culture on a type 4 extracellular matrix (see Figure 20-22). After two weeks they formed epithelial sheets that resembled villi in structure. Staining of these organoids for specific marker proteins showed that they contained all four differentiated epithelial cell types: (a) villin, green, a marker protein for the absorptive enterocytes that are localized near the apical (luminal, Lu) surface of these cells; (b) Muc2, red, goblet cells; (c) lysozyme, green, Paneth cells; and (d) chromogranin A, green, enteroendocrine cells. The organoids were also stained with DAPI (blue) to reveal nuclei. [From T. Sato et al., 2009, *Nature* 459:262.]

Delta protein, that are essential for intestinal stem-cell maintenance. Co-culturing of intestinal stem cells with Paneth cells markedly improved the formation of intestinal villus-like structures, and genetic manipulations in mice that caused a reduction of Paneth cell numbers concomitantly caused a reduction in intestinal stem cells. Thus Paneth cells, which are progeny cells of the intestinal stem cells—also constitute much if not all of the niche for intestinal stem cell maintenance.

Neural Stem Cells Form Nerve and Glial Cells in the Central Nervous System

The great interest in the formation of the nervous system and in finding better ways to prevent or treat neurodegenerative diseases has made the characterization of neural stem cells an important goal. The earliest stages of vertebrate neural development involve the rolling up of a tube of ectoderm (the cell layer that lines the outside of the embryo) that extends the length of the embryo from head to tail (Figure 21-15a).

FIGURE 21-15 Formation of the neural tube and division of neural stem cells. (a) Early in vertebrate development a part of the ectoderm rolls up and separates from the rest of the cells. This forms the epidermis (gray) and the neural tube (blue). Near the interface between the two, neural crest cells form and then migrate to contribute to skin pigmentation, nerve formation, craniofacial skeleton, heart valves, peripheral neurons, and other structures. The notochord, a rod of mesoderm for which we are named (chordates), provides signals that affect cell fates in the neural tube. The interior of the neural tube will become a fluid-filled series of chambers called ventricles. Neural stem cells located adjacent to the ventricles, described as being in the subventricular zone (SVZ), will divide to form neurons that migrate radially outward to form the layers of the nervous system. (b) Neural stem cells in the subventricular zone can divide symmetrically (top) to give rise to two stem cells, side by side, both in contact with the ventricle. Alternatively stem cells can divide to produce one daughter that is a stem cell able to self-renew and another daughter, termed a transiently amplifying (TA) cell, which begins to migrate and differentiate (bottom). A key difference between the two patterns of division is the orientation of the mitotic spindle. [Adapted from L. R. Wolpert et al., 2001, *Principles of Development*, 2d ed., Oxford University Press.]

This *neural tube* will form the brain and spinal cord. Initially the thickness of the tube is a single layer of cells, and these cells, the embryonic neural stem cells (NSCs), will give rise to the entire central nervous system. The inside of the neural tube will form the fluid-filled compartments called *ventricles*, and the lining of the neural tube, where most cell division takes place, is called the *subventricular zone* (SVZ). The SVZ has properties of a stem-cell niche.

Labeling and tracing experiments have been done to determine how cells are born and where they go after birth. The embryonic neural stem cells that line the ventricle can divide symmetrically, producing two daughter stem cells side by side (Figure 21-15b). Alternatively they can divide asymmetrically, producing a cell that remains a stem cell and another that migrates radially outward. The migrating cells are often called *transient amplifying* (TA) cells because they divide rapidly multiple times to form the neural precursors called neuroblasts. Once formed, TA cells and neuroblasts migrate radially outward and form successive layers of the neural tissue in an inside-out fashion. In contrast to TA cells and neuroblasts, the stem cells remain in contact with the ventricle (see Figure 21-15b). Newly formed cells therefore traverse the layers of preexisting cells before taking up residence on the outside.

Tracing experiments with viruses have shown that a neuroblast can produce two daughters, one a neuron and one a glial cell. The experiment was done by preparing a library of retroviruses, each one containing a unique DNA sequence, so that any cell infected by a single virus would give rise to a clone of cells that all carry that particular virus's DNA sequence. In this way, all the cells that derived from a single NSC or TA precursor could be identified as a clone (Figure 21-16). The results of the experiment were surprising. First, some neurons were found to have migrated considerable distances laterally, abandoning their radial migration to the outer cortical layer. Second, in some cases, a single neuron

and a single glial cell shared the same viral DNA sequence. A neural precursor had evidently been infected and had then divided once to give rise to two quite different cell types.

For many years it was believed that no new nerve cells are formed in the adult. Most mammalian brain cells indeed stop dividing by adulthood, but some cells in the subventricular zone and in a region near the hippocampus continue to act as stem cells to generate new neurons (Figure 21-17). Similar to other types of stem cells, these neural stem cells are functionally defined by their ability to self-renew and differentiate into neural lineages, including neurons, astrocytes, and oligodendrocytes. To identify and characterize neural stem cells, cells isolated from the subventricular zone were cultured with growth factors such as FGF2 or EGF. Some of the cells survived and proliferated in an undifferentiated state; that is, they could self-renew. In the presence of other hormones these undifferentiated cells gave rise to neurons, astrocytes, or oligodendrocytes. The successful establishment of self-renewing and multipotent cells from the adult brain provides strong evidence for the presence of nerve stem-cell populations.

Some of the NSCs in the SVZ have some properties of astrocytes, such as producing glial fibrillary acidic protein (GFAP). But these NSCs can divide asymmetrically to reproduce themselves and to produce transient amplifying cells that in turn divide to form neural precursors (neuroblasts). The subventricular niche is created by mostly unknown signals from the ependymal cells that form a layer just inside the neural tube (lining the ventricle) and by endothelial cells that form blood vessels in the vicinity (see Figure 21-17). The endothelial cells, and the basal lamina they form, are in direct contact with NSCs and are believed to be essential in forming the neural stem cell niche. Each neural stem cell extends a single cilium through the ependymal cell layer to directly contact the ventricle. Though the function of the cilium is unknown, it is irresistible to consider it as a possible

EXPERIMENTAL FIGURE 21-16 Retrovirus infection can be used to trace cell lineage. (a) Engineered viral genome.

The long terminal repeats (LTRs) are standard retroviral repeats. Viral proteins required for infection are encoded in the *gag* and in *A-env* genes. PLAP is an introduced gene for an alkaline phosphatase. Detection of this enzyme by histochemical staining is used to determine which cells carry a virus. The oligonucleotide sequence, synthesized by providing random nucleotides, is different in each virus and can be amplified by PCR, using primers for sequences that are in all viruses (blue arrows) and then sequenced. A library of more than 10^7 distinct viruses was made. Because these viruses lack the genes required for production of new virions in infected cells, each defective virus can infect a cell only once, becomes stably integrated into the genome, and is expressed in that cell and all its descendants. (b) Tissue section showing cells infected with defective viruses. The DNA from each stained clone of cells can be extracted and amplified by PCR to determine the sequence of the infecting virus. Cells descended from the same initially infected cell will have the same oligonucleotide sequence, whereas separate infection events will give different sequences. [From J. A. Golden et al., 1995, *Proc. Nat'l. Acad. Sci. USA* 92:5704.]

(a) Cross section of whole developing brain

antenna that may receive signals that would otherwise be inaccessible to the cell. The signals that create the niche are not completely characterized, but there is evidence for a blend of factors, including FGFs, BMPs, IGF, VEGF, TGF α , and BDNF. The BMPs appear to favor astrocyte differentiation over neural differentiation, one example of cell fate determination control that must remain in proper balance.

Hematopoietic Stem Cells Form All Blood Cells

Another continuously replenished tissue is the blood, whose stem cells are located in the embryonic liver and in bone marrow in adult animals. The various types of blood cells

FIGURE 21-17 Neural stem cell niche in the adult brain.

(a) Cross section of the developing nervous system showing the lateral ventricle, a fluid-filled space inside the neural tube. The area just surrounding the ventricle, called the subventricular zone, is the site of neural stem cells, from which neural precursors emerge. (b) In both the embryonic and adult brain, different types of neural stem cells are located in the subventricular zone and are classified by their self-renewal and differentiation capacities, possibly representing their linear transition during neurogenesis. The type B neural stem cells express the astrocyte marker glial fibrillary acidic protein (GFAP) and are exposed to the ventricle and contact blood vessels via the apical cilia and basal ends, respectively. Type B cells have the potential to produce actively dividing (transiently amplifying) neural progenitor cells, and these subsequently generate the neuroblasts that will differentiate into neurons. [(b) Adapted from H. Suh et al., 2009, *Annu. Rev. Cell Dev. Biol.* 25:253.]

all derive from a single type of multipotent *hematopoietic stem cell* (HSC), which gives rise to the more restricted myeloid and lymphoid progenitor stem cells that are capable of limited self-renewal (Figure 21-18). After HSCs form, numerous extracellular growth factors called **cytokines** regulate proliferation and differentiation of the precursor cells for various blood-cell lineages. Each branch of the cell-lineage tree has different cytokine regulators, allowing exquisite control of the production of specific cell types. If all blood cells are needed, for example after a bleeding injury, multiple cytokines can be produced. If only one cell type is needed, for example when a person is traveling at high altitude, **erythropoietin** is made by the kidney and stimulates the terminal proliferation and differentiation of CFU-E precursors but not other types of precursors. Erythropoietin activates several different intracellular signal transduction pathways, leading to changes in gene expression that promote formation of erythrocytes (see Figures 16-10 and 16-12). Similarly, G-CSF, a different cytokine, will stimulate proliferation and differentiation of bipotential GM-CFC macrophage/granulocyte progenitors into granulocytes, while M-CSF stimulates production of macrophages from the same progenitor cell.

The hematopoietic lineage was originally elucidated by injecting the various types of precursor cells into mice whose precursor cells had been wiped out by irradiation. By observing which blood cells were restored in these transplant experiments, researchers could infer which precursors or terminally differentiated cells (e.g., erythrocytes, monocytes) arise from a particular type of precursor.

Like other stem cells, HSCs are residents of a niche. One major cell type in the bone marrow niche is osteoblasts, bone-forming cells that are localized to the bone surface. A Delta-like ligand and proteins such as stem-cell factor (SCF), produced by niche cells, signal to Notch and SCF receptors on the surface of HSCs. Several other growth factor–receptor pairs also stimulate the HSCs, and probably other types of cells participate in forming the HSC niche.

FIGURE 21-18 Formation of blood cells from hematopoietic stem cells in the bone marrow. Multipotent long-term repopulating hematopoietic stem cells may divide symmetrically to self-renew (blue curved arrow) or divide asymmetrically to form one daughter cell that is multipotent like the parental stem cell and another daughter with limited self-renewal capability. Ultimately this daughter generates myeloid and lymphoid stem cells; although these multipotent cells are capable of limited self-renewal, they are committed to one of the two major hematopoietic lineages. Depending on the types and amounts of cytokines present, the myeloid and lymphoid stem cells undergo rapid rounds of cell division and generate different types of progenitor cells (dark green). These progenitors are termed multipotent or unipotent in that they can give rise to several or only a single type of differentiated

blood cell, respectively; they respond to one or a few specific cytokines. These progenitors are detected by their ability to form colonies containing the differentiated cell types shown at right, measured as *colony-forming cells (CFCs)*. The colonies are detected by plating the progenitor cells in a viscous medium, formed by a polymer such as methylcellulose, such that all of the daughter differentiated cells remain localized and thus form a colony. Some of the cytokines that support this process are indicated (pink labels). GM = granulocyte-macrophage; Eo = eosinophil; E = erythrocyte; mega = megakaryocyte; T = T cell; B = B cell; CFU = colony-forming unit; CSF = colony-stimulating factor; IL = interleukin; SCF = stem-cell factor; Epo = erythropoietin; Tpo = thrombopoietin. [Adapted from M. Socolovsky et al., 1998, *Proc. Nat'l. Acad. Sci. USA* **95**:6573, and N. Noverstern et al., 2011, *Cell* **144**:296.]

Hematopoietic stem cells were detected and quantified by bone marrow transplantation experiments (Figure 21-19). The first step in these experiments was separation of the different types of hematopoietic precursors. This sorting is possible because hematopoietic stem cells and each type of progenitor produce unique combinations of cell-surface proteins that can serve as cell-type-specific markers. If bone marrow extracts are treated with fluorochrome-labeled antibodies for these markers, cells with different surface markers can be separated in a fluorescence-activated cell sorter (see Figures 9-2 and 9-3). Remarkably, such transplantation experiments revealed that a single HSC is sufficient to restore the entire blood system of an irradiated mouse. After transplantation the stem cell takes up residence in a niche in the bone marrow and divides to make more stem cells and also progenitors of the different blood lineages.

 The first human bone marrow transplant was done in 1959, where a patient with end-stage (fatal) leukemia was irradiated to destroy her cancer cells. She was transfused with bone marrow cells from her identical twin sister, thus avoiding an immune response, and was in remission for three months. This pioneering beginning, which was rewarded with the Nobel Prize in Medicine in 1990, led to present-day treatments that can often lead to a complete cure of many cancers. The stem cells in the transplanted marrow can generate all types of functional blood cells, and transplants are useful in patients with certain hereditary blood diseases, including many genetic anemias (insufficient red-cell levels), genetic defects of blood cells such as the hemoglobin disorder sickle-cell anemia, and in cancer patients who have received irradiation and/or chemotherapy. Both chemotherapy and irradiation destroy the bone marrow cells as well as cancer cells. ■

EXPERIMENTAL FIGURE 21-19 Functional analysis of hematopoietic stem cells by bone marrow transplantation. The two strains of mice are genetically identical except for the gene encoding a protein, termed Ly5, found on the surface of all nucleated blood cells, including all T and B lymphocytes, granulocytes, and monocytes. The proteins encoded by the two alleles of the gene, Ly5.1 and Ly5.2, can be detected by specific monoclonal antibodies. A recipient Ly5.2 mouse is lethally irradiated, then injected with stem cells purified from a Ly5.1 strain. Because the stem cells take weeks or months to produce differentiated blood cells, the recipient mouse will die unless it receives bone marrow progenitor cells from a genetically identical mouse (termed “supportive” cells) that will produce mature blood cells for the first few weeks after the transplant. At intervals after the transplant, blood or bone marrow is recovered and reacted with a blue-fluorescing monoclonal antibody to Ly5.1 and a red-fluorescing monoclonal antibody to Ly5.2. Mature blood cells that are descended from the donor stem cell are detected by FACS analysis, seen here as cells that fluoresce blue and not red. These cells can be sorted and stained with fluorescent antibodies specific for marker proteins found on different types of mature blood cells to show that a stem cell indeed is pluripotent, in that it can generate all types of lymphoid and myeloid cells. [Courtesy Dr. Chengcheng (Alec) Zhang.]

The frequency of hematopoietic stem cells is about 1 cell per 10^4 bone marrow or embryonic liver cells. During embryonic life, stem cells often divide symmetrically, producing two daughter stem cells (see Figure 21-8); this allows the number of stem cells to increase over time and produce the large number of progenitor cells required to make all of the necessary blood cells before birth. In adult animals, hematopoietic stem cells are largely quiescent, “resting” in the G_0 state in the bone marrow stem cell niche. When more blood cells are needed, one or more of these cells undergoes asymmetric division, forming

one stem cell like the parent and a rapidly proliferating cell that generates the progenitors illustrated in Figure 21-18.

You have probably noticed that all the molecular regulators of stem cells are familiar proteins (see Chapters 15 and 16) rather than dedicated regulators that specialize in stem-cell control. Each type of signal is used repeatedly to control cell fates and growth. These are ancient signaling systems, at least a half billion years old, for which new uses have emerged as cells, tissues, organs, and animals have evolved new variations.

Meristems Are Niches for Stem Cells in Plants

As in their multicellular animal counterparts, the production of all tissues and organs in plants relies on small populations of stem cells. Like animal stem cells, these stem cells are defined by their ability to undergo self-renewal and also to undergo asymmetric division to generate daughter cells that produce differentiated tissues. Plant stem cells reside in specialized microenvironments, stem-cell niches where extracellular signals are produced that maintain the stem cells in a multipotent state. But since the signals that pass between stem and supportive cells are very different in these two kingdoms, stem cells and niches in plants and animals likely evolved by different pathways.

Plant stem cells are located in niches called **meristems**, which can persist for thousands of years in long-lived species such as bristlecone pines. The body axis of the plant is defined by two primary meristems that are established during embryogenesis, the *shoot apical meristem* and the *root apical meristem*. In contrast to animals, very few tissues or organs are specified during plant embryogenesis. Instead, organs such as leaves, flowers, and even germ cells are continuously generated as the plant grows and develops. The aboveground part of the plant is derived from the shoot apical meristems and the belowground part from the root apical meristems. Stem-cell identity is maintained by cellular position, rather than lineage, and intercellular signals such as hormones, mobile signaling peptides, and miRNAs.

Slowly dividing pluripotent stem cells are located at the apex of the shoot apical meristem, with more rapidly dividing multipotent “transiently amplifying” daughter cells on the periphery. Descendants of the shoot stem cells are displaced to the periphery of the meristem and are recruited to form primordia of new organs, including leaves and stems. Division ceases as cells acquire characteristics of specific cell types, and most organ growth occurs by cell expansion and elongation. New shoot stem cell niches can form in the axils of leaf primordia, which then grow to form lateral branches (Figure 21-20a). Floral meristems in turn give rise to the four floral organs—sepals, stamens, carpels, and petals—that form flowers. Unlike shoot apical meristems, floral meristems gradually become depleted as they give rise to the floral organs.

Genes required for stem-cell identity, maintenance, and cell differentiation have been defined by genetic screens for mutants exhibiting larger, smaller, or non-replenishing meristems and more recent gene expression profiling of isolated meristem cell populations. One shoot apical meristem determinant is a homeodomain transcription factor gene called

FIGURE 21-20 Physical structure and regulatory networks in the shoot meristems of *Arabidopsis*. The reproductive shoot apical meristem produces shoots, leaves, and more meristem. Flower production occurs when the meristem switches from leaf/shoot production to flower production, accompanied by an increase in the number of meristem cells that form floral meristems, as shown here. (a) Three-dimensional images of shoot meristems and floral meristems based on reconstruction of confocal images. Key regions of the meristems are marked in false colors: red for the stem cells, blue for the supportive cells that produce stem-cell maintenance signals, and yellow for the rib meristem. (b) Transverse section through the apex of the meristem showing *CLV3* expression in stem cells (red) and *WUS* expression in the supportive cells (blue). The stem cells produce daughters by asymmetric division in the direction of the arrows. (c) Secreted *CLV3* protein (red balls) represses *WUS* transcription in supportive cells; the *CLV1* receptor and associated proteins are marked. [Part (a) after Robert Sablowski, 2011, *Curr. Opin. Plant Biol.* 14:4; parts (b) and (c) after Ben Scheres, 2007, *Nat. Rev. Mol. Cell Biol.* 8:345.]

WUSCHEL (*WUS*). *WUS* is required for maintenance of the stem-cell population but is expressed in the supportive cells underlying the stem cells, thus suggesting that these cells are analogous to a stem-cell niche in metazoan animals (Figure 21-20b). *WUS* promotes the expression of *CLAVATA3* (*CLV3*) in the stem cells. *CLV3* encodes a small secreted peptide that in turn binds to the *CLV1* receptor on the supportive cells and negatively regulates *WUS* expression. Thus a negative feedback loop between *WUS* and *CLV3* maintains the size of the stem-cell population (Figure 21-20c). Other signals, such as the plant hormone cytokinin, are also important in regulating *WUS* expression. Root apical meristem maintenance and function is in many ways conceptually similar, although the specific genes and hormones involved are distinct.

Plants have an amazing capacity for regeneration. The home gardener will be familiar with the ability of leaf or stem cuttings to form roots with little inducement beyond a glass of water and a sunny windowsill. Experiments performed in the middle of the last century demonstrated that single cells isolated from carrot roots could regenerate entire plants when placed on media containing the appropriate mix of nutrients and hormones. Since that time, an often-cited major difference between plant and animal cells was that all plant cells are totipotent. However, with the ability to generate iPS cells from differentiated animal cells and more recent careful analyses of the cells contributing to plant regeneration, which suggest that regenerated tissue arises from preexisting populations of stem cells rather than through a process of dedifferentiation, this distinction is becoming blurred. ■

KEY CONCEPTS of Section 21.2

Stem Cells and Niches in Multicellular Organisms

- Stem cells are multipotent and undifferentiated; they can undergo self-renewal such that their number remains constant or increases over the organism's lifetime.
- Multipotent stem cells are formed in niches that provide signals to maintain a population of nondifferentiating stem cells. The niche must maintain stem cells without allowing their excess proliferation, and must block differentiation.
- Stem cells are prevented from differentiating by specific controls that operate in the niche. A high level of β -catenin, a component of the Wnt signaling pathway, has been implicated in preserving stem cells in the germ line and intestine by directing cells toward self-renewal division rather than differentiation states.
- Germ-line cells give rise to eggs or sperm. By definition, all other cells are somatic cells.
- In worm and fly gonads one or a few cells form the germ stem cell niche, sending signals directly to the adjacent stem cells. Daughter cells that cannot contact the niche cells undergo proliferation and differentiation into germ cells (see Figures 21-9 and 21-10).
- Populations of stem cells associated with the intestinal epithelium, brain, and many other tissues regenerate differentiated tissue cells that are damaged, sloughed, or become aged (see Figures 21-11, 21-15, and 21-18).
- Intestinal stem cells reside in the base of intestinal crypts, adjacent to Paneth cells, which form part of the niche, and are marked by expression of the *Lgr5* receptor.
- Neural stem cells are found in the subventricular zone of the brain both during development and adulthood and generate both nerve and glial cells (see Figure 21-17).
- In the blood-cell lineage, different precursor types form and proliferate under the control of distinct cytokines (see Figure 21-18). This allows the body to specifically induce the replenishment of some, or all, of the necessary types.

- Plant stem cells persist for the life of the plant in the meristem. Meristem cells can give rise to a broad spectrum of cell types and structures (see Figure 21-20).

21.3 Mechanisms of Cell Polarity and Asymmetric Cell Division

We have discussed the importance of asymmetrical division in generating cell diversity during development and also when stem cells divide to give rise to one stem cell and one differentiated cell. What mechanisms underlie the ability of cells to become asymmetric before cell division to give rise to cells with different fates? Cell asymmetry is a concept we have met before, under the name of cell **polarity**, so let us first review what it means for a cell to be polarized.

FIGURE 21-21 General features of cell polarity and asymmetric cell division. (a) Cell polarity requires specific determinants, including mRNAs, proteins, and lipids, to be asymmetrically localized in a cell. If the mitotic spindle is positioned so that these determinants are segregated during cell division, the two daughter cells will have different cell fate determinants. However, if the mitotic spindle is not oriented appropriately, the determinants will not be segregated properly and the daughter cells could have the same fate (not shown). (b) General hierarchy of the steps in generating a polarized cell. To know in which orientation to polarize, cells have to be exposed to a spatial cue **1**. They need to have receptors or other mechanisms to

Cell polarity—the ability of cells to organize their internal structure, resulting in changes of cell shape and regions of the plasma membrane with different protein and lipid compositions—has been introduced in several chapters. For example, we discussed how polarized epithelial cells have an apical domain with abundant microvilli separated from the basolateral domain by tight junctions (see Figures 17-1 and 20-9). To function in epithelial transport requires these cells to have different transporter proteins in the apical and basolateral membranes (Figure 11-30). As indicated earlier, not only epithelial cells but essentially all cells in the body are polarized to provide their physiological function. If a polarized cell divides and gives rise to two different daughter cells, it is said to have undergone **asymmetric cell division** (Figure 21-21a). Thus establishing cell polarity is an integral part of achieving asymmetric cell division—a cell must become polarized before dividing in order to give two different daughter cells.

sense the cue **2**. After sensing the cue, signal transduction pathways **3** regulate the cytoskeleton (microtubules and/or microfilaments, depending on the system) to reorganize it in the appropriate polarized manner **4**. The polarized cytoskeleton provides the framework for the transport of membrane trafficking organelles and macromolecular complexes, including fate and polarity determinants, in the cell **5**. In many cases the polarity is reinforced by returning polarity determinants that have moved from the polarization site. In cases where the determinants are membrane proteins, this reinforcement cycle involves uptake by endocytosis and delivery to the polarization site **6**.

Cell Polarization and Asymmetry Before Cell Division Follow a Common Hierarchy

The polarization of a cell, whether to polarize with or without cell division, follows a general pattern, diagrammed in Figure 21-21b. In order to know in which direction to polarize, or become asymmetric, a cell must have available specific cues that provide it with spatial information (step 1). As we will see, such cues can be localized soluble factors or signals from other cells and/or the extracellular matrix. To be receptive to these cues, cells have appropriate receptors on their surface or other machinery to sense the cues (step 2). Once the cues have been detected, the cell has to respond appropriately by processing the incoming signal into spatial information to define the orientation of the polarity (step 3). Generally, the next step involves the local reorganization of cytoskeletal elements, notably microfilaments and microtubules (step 4). Now that the cell has structural asymmetry, to achieve full polarity, including molecular asymmetry, molecular motors direct the trafficking of polarity factors, that, depending on the system, may be cytoplasmic proteins and/or membrane proteins synthesized by the secretory pathway to their appropriate locations (step 5). As we will see, in the case of many polarized cells, the polarity can often be reinforced or maintained through concentration of the polarity determinants by moving them from sites of lower concentration back to the polarized site (step 6).

In the next section, we discuss a simple cell that shows asymmetry—a yeast cell during mating. In later sections, we turn to animal cells, where conserved polarity proteins are instrumental in interpreting polarity cues and generating cell asymmetry prior to cell division. We then describe how these same polarity proteins are used to polarize epithelial cells and finally discuss aspects of asymmetric division in stem cells.

Polarized Membrane Traffic Allows Yeast to Grow Asymmetrically During Mating

One of the simplest and best-studied forms of cell asymmetry occurs when budding yeast cells mate (see Figure 16-23). Yeast can exist in a haploid state (a single copy of each chromosome) or diploid state (two copies of each chromosome). The haploid state can exist in either of two mating types (“sexes”), called *a* or α . The preferred state of yeast in nature is the diploid state, so *a* cells are always looking to mate with α cells to restore the diploid state. Each haploid cell type secretes a specific mating pheromone—a *a* cells secrete a factor and α cells secrete α factor—and each express on their surface a receptor that senses the pheromone of the opposite mating type. Thus *a* cells have a receptor for α factor and α cells have a receptor for *a* factor. When you place cells of opposite mating types near each other, the receptors on each cell type bind and detect the pheromone cue of the other cell and determine its spatially highest concentration in order to know in which direction to mate. When the cells detect the opposite mating factor, two important processes occur. First, they synchronize their cell cycles by arresting at G_0 so that when they mate, the two haploid genomes will be at the same stage of

the cell cycle. Second, they target cell growth in the direction of the pheromone to assemble a mating projection called a “shmoo.” If shmooing cells of opposite mating types touch, they will fuse at the shmoo tips and then the haploid nuclei will come together to restore the diploid state. Under conditions of plentiful nutrients, the diploid yeast cells proliferate. However, under conditions of starvation, they undergo meiosis to form stress-resistant haploid spores. When nutrients return, the spores germinate and proliferative haploid cells can grow and then mate to restore the diploid state.

By looking for mutants in yeast haploids that cannot shmoo in response to the opposite mating pheromone, researchers have identified how the asymmetric growth necessary for shmoo formation occurs (Figure 21-22). As might be anticipated, this mechanism initially involves a signal transduction pathway that establishes a polarized cytoskeleton, which in turn guides membrane traffic to the appropriate location for asymmetric growth. Activation of the mating factor receptor—a typical G protein-coupled receptor (see Figure 15-15)—results in the localized accumulation and activation of the small GTPase Cdc42 in the region of the cytoplasm closest to the pheromone source (Figure 21-22, step 1). As we discussed in Chapter 17, small GTPases of the Rho family, of which Cdc42 is a member, regulate the assembly of the actin cytoskeleton (see Figures 17-42 and 17-43). This GTPase exists as the Cdc42-GDP inactive form and can be activated by a specific guanine nucleotide exchange factor (GEF) to the active Cdc42-GTP form. In the active form it binds and activates effector molecules. During mating, activation of the receptor leads to localized recruitment and activation of the GEF for Cdc42, thus providing localized active Cdc42-GTP. This active Cdc42-GTP leads to the local activation of a formin protein (step 2). As we have also discussed in Chapter 17, formin proteins nucleate the assembly of polarized actin filaments, with the (+) end of the filament remaining bound to the formin (see Figure 17-13). This now provides the tracks for the transport of secretory vesicles by a myosin-V motor to the (+) ends of the filaments for localized growth and hence shmoo formation (step 3). Notice that this mechanism requires the accumulation of polarity proteins, which includes Cdc42-GTP, to remain concentrated at the growing shmoo tip. To ensure that this polarity is maintained during shmoo growth, a directed endocytic cycle is believed to exist. In this cycle, Cdc42 that has diffused and moved away from the polarization site is internalized by endocytosis and transported back to the shmoo tip, thereby reinforcing the polarity (step 4).

The Par Proteins Direct Cell Asymmetry in the Nematode Embryo

The nematode worm, *Caenorhabditis elegans*, has provided a powerful model system for understanding development. The reason it was selected for study is that the animal is transparent, has a rapid life cycle, has excellent genetics, and the lineage of cells from the one-cell embryo to the adult of 959 somatic cells is invariant (Figure 21-23a, c). A critical aspect of this lineage is the first cell division, where the P0 cell—the

FIGURE 21-22 Mechanism of shmoo formation in yeast. (a) The haploid yeast cell needs to grow toward the highest concentration of mating factor, so it has a receptor on its surface that signals the cell towards the highest concentration. This signal induces the localization and activation of the small GTPase, Cdc42, to generate a higher concentration of Cdc42-GTP at this site **1**. The Cdc42-GTP locally activates a formin to nucleate and elongate actin filaments from this site **2**. Because formins bind to the (+) end of actin filaments, this end is oriented toward Cdc42-GTP and the highest concentration of the mating factor. A myosin-V motor transports secretory vesicles along the actin filament, resulting in the growth of the shmoo **3**. The polarity of the shmoo is reinforced by an endocytic cycle that constantly returns diffusing polarity factors, such as Cdc42, back along the actin filaments to the polarization site **4**. (b) DIC light-microscope image of a shmooing yeast cell. [From http://commons.wikimedia.org/wiki/File:Shmoo_yeast_S_cerevisiae.jpg.]

fertilized egg, or zygote—gives rise to the AB and P1 cells by an asymmetric cell division, and each of these two cells gives rise to different lineages. Much is known about this first asymmetric division, which is where we focus our attention.

Before the first cell division, the zygote is visibly asymmetric: cytoplasmic complexes called P granules are concentrated at the posterior end of the cell (Figure 21-23b). It turns out that during further cell divisions, these P granules always concentrate in cells that will eventually become the germ line, where they ultimately play an important role in germ-line development. As mentioned previously, the first asymmetric division of the P0 cell gives rise to the P1 cell and the larger AB cell. Following that, at the two-cell stage, the mitotic spindles are arranged at right angles to one another so that the ensuing cell divisions are also at right angles to one another (Figure 21-24a). To begin to understand how this first essential asymmetric division occurs, mutations were identified in six different genes that resulted in a symmetric first division. Since the P granules were not partitioned correctly in these mutants, the genes identified in this study were called partition defective, or *par* genes. In these mutants, P granules do not properly localize to the posterior end of the zygote, and the mitotic spindles are not oriented correctly in preparation for the second division (Figure 21-24a). A key insight came when the products of the *par* genes, namely the Par proteins, were localized. In wild-type zygotes, many of the Par proteins localize either at the cortex of the anterior half of the cell or at the cortex of the posterior half. For example, Par3 (as part of a larger complex comprising Par3, Par6, and aPKC—atypical protein kinase C) localizes anteriorly, while Par2 and Par1 localize posteriorly (Figure 21-24b). Subsequent work has shown that *antagonistic interactions* exist between these protein complexes; that is, if the Par3, Par6, aPKC complex is localized to one region, it excludes Par2 and vice versa. This is shown by the finding that the Par3, Par6, aPKC complex spreads over the whole cortex in *par2* mutants and Par2 spreads over the whole cortex in *par3* or *par6* mutants. The molecular nature of this antagonism is not fully understood, but part of it is mediated by the protein kinase aPKC phosphorylating Par2 to inhibit its ability to bind to the anterior cortex.

VIDEO: Time-Lapse Imaging of *C. elegans* Embryogenesis

FIGURE 21-23 Cell lineage in the nematode worm *C. elegans*.

(a) Pattern of the first few divisions, starting with P0 (the zygote) and leading to formation of the six founder cells (yellow highlights). The first division is asymmetric, giving rise to the AB and P1 cells. The EMS cell is so named because it gives rise to most of the endoderm and mesoderm. The P4 lineage gives rise to the cells of the germ line.

(b) Micrographs of two, four and eight cell embryos with DNA stained in blue, nuclear envelope in red, and P granules in green. The P1, P2 and P3 cells, that will give rise to the germ line, are indicated.

(c) The full lineage of the entire body of the worm, showing some of the tissues formed. [Part (b) from Susan Strome and Dustin Updike.]

EXPERIMENTAL FIGURE 21-24 Par proteins are asymmetrically localized in the one-cell worm embryo. (a) DIC images of wild type and *par3* mutant embryos. Notice that in wild-type cells, the AB cell is larger than the P1 cell, whereas they are the same size in the *par3* mutant. The *par3* mutant also has a defect in spindle orientation and

P-granule (red) segregation. DNA is stained blue. (b) Complementary localization of the anterior Par complex (Par3, Par6, aPKC) (red) and posterior determinants (green) in the one-cell embryo. [Parts (a) and (b) courtesy of Diane Morton and Kenneth Kemphues.]

FIGURE 21-25 Mechanism of segregation of the anterior Par complex in the one-cell worm embryo. (a) Before fertilization, the cell cortex is under tension due to the activity of Rho-GEF, the exchange factor for the small GTPase, Rho. Rho-GTP activates Rho kinase, which phosphorylates the regulatory light chain of myosin II to activate it. Together with actin filaments, the active myosin II maintains tension in the cell cortex. (b) Localization of myosin II before (top) and after (bottom) fertilization. The asterisk marks the region of sperm entry. (c) Before fertilization, as the Rho-GEF is uniformly active, the cortex is under tension from the active myosin II, and the anterior Par complex (Par3/Par6/aPKC) is uniformly distributed around the cortex. On fertilization by sperm, the Rho-GEF becomes locally reduced, resulting in local deactivation of myosin II. This generates unequal tension, so the actin–myosin II contracts toward the future anterior end, moving the anterior Par complex with it. Once the anterior complex is localized, factors such as Par2 associate with the posterior cell cortex. [Part (b) from E. Munro et al., 2004, *Dev. Cell* 7:413–424; panel (c) modified from D. St. Johnston and J. Ahringer, 2010, *Cell* 141:757–774.]

What defines the orientation of the asymmetry in the one-cell embryo? It turns out that the asymmetry is defined by the sperm entry site, which becomes the posterior end. Prior to sperm entry, the entire egg cortex is under tension provided by an actin meshwork containing active myosin II (Figure 21-25). As we discussed in Chapter 17, myosin II can form bipolar filaments that pull on actin filaments to generate tension, as is also seen in muscle and the contractile ring. Myosin II activity is regulated by a signal transduction pathway involving the small GTPase Rho (see Figure 17-42). In the unfertilized egg, Rho is maintained in its active Rho-GTP state by the uniform distribution of its activator, the nucleotide exchange factor Rho-GEF. Rho-GTP activates Rho kinase, which phosphorylates the myosin light chain of myosin II to activate it (Figure 21-25a). Sperm entry results in the local depletion of the Rho-GEF, necessary to maintain active Rho. Thus sperm entry defines the posterior region by depleting the Rho-GEF, thereby lowering active myosin II. With this local reduction in the contractile activity, the acto-myosin network contracts toward the anterior (Figure 21-25b), and as it does so, it drags (in an unknown manner) the anterior complex containing Par3, Par6, and aPKC to that end (Figure 21-25c). With the removal of the anterior complex, Par2 can now occupy the posterior cortex, and cell asymmetry is established.

It turns out that another component, Cdc42, is needed to maintain the initial asymmetry induced by the acto-myosin contraction. The active form of this GTPase, Cdc42-GTP, binds Par6 and is necessary for maintaining the complex at the anterior end, although the mechanism for this localization is not yet clear. Recent work has also implicated an endocytic reinforcement cycle, like we discussed for yeast shmoo formation, to maintain polarity. Thus the steps of

responding to a cue, establishing asymmetry, and maintaining asymmetry are conserved features of both systems.

The Par Proteins and Other Polarity Complexes Are Involved in Epithelial-Cell Polarity

In vertebrates, polarized epithelial cells use cues from adjacent cells and the extracellular matrix to orient their axis of polarization. The process of polarization is quite similar in epithelial cells of vertebrates and the fruit fly *Drosophila melanogaster*. Much of our knowledge has come from the fly system because of the ease with which mutants can be isolated and analyzed.

FIGURE 21-26 Polarity establishment in epithelial cells.

(a) Polarity determination in epithelial cells is also driven by the apical Par complex. Intricate and antagonistic interactions of the Par complex with both the basal Scribble complex and the apical Crumbs complex leads to establishment and maintenance of epithelial-cell polarity. The localization of the different complexes to membrane domains is indicated by colored bars, with the Scribble complex associating with the lateral membrane, the apical Par complex with the region at the

cell junctions, and the Crumbs complex immediately apical to the Par complex. Functional epithelial polarity is maintained both by (b) a polarized cytoskeleton and (c) membrane trafficking pathways. In the biosynthetic pathway, proteins and lipids destined for the apical and basolateral domains are sorted in the Golgi complex and transported to their respective surface (red arrows). Endocytic pathways (blue arrows) regulate the abundance of proteins and lipids on each surface and sort them between surfaces by transcytosis.

Genetic screens in the fly have uncovered multiple genes necessary for the generation of epithelial-cell polarity. Analysis of the phenotypes of the mutants and proteins encoded by these genes has identified three major groups of proteins: the complex of Par3, Par6, and aPKC (in this system known as the *apical Par complex*), the Crumbs complex, and the Scribble complex. By extensive analyses of the effects of these complexes on each other when individual components are missing, a general interpretation of their contributions to epithelial-cell polarization has been achieved, although a detailed molecular understanding is still emerging (Figure 21-26a).

The first known step in epithelial-cell polarization is the interaction between adjacent cells, which in vertebrate cells is through nectin, a cell-adhesion molecule in the Ig superfamily, and a junctional protein called JAM-A. These interactions signal the cells to recruit the Par complex and to assemble adherens and tight junctions (see Figure 20-1). The Crumbs complex is recruited more apically than the Par complex, and the Scribble complex defines the basolateral surface. In the absence of the Par complex, cells cannot polarize, and it is, like in the nematode embryo, the master regulator of cell polarity. In the absence of the Scribble complex, the apical domain is greatly expanded, whereas in the absence of Crumbs, the apical domain is greatly reduced. This has led to the idea that there are antagonistic relationships between these complexes, with the apical Crumbs complex antagonizing the basolateral Scribble complex (see Figure 21-26a). Thus as is the case in the worm embryo, asymmetry is mediated by complexes working antagonistically against each other.

In a manner that is only partially understood, this arrangement of polarity proteins reorganizes the cytoskeleton, with

distinct organizations of microfilaments making up the apical and basolateral membranes. Microtubules are rather unusual in their distribution, with lateral microtubules orienting their (–) ends toward the apical domain and other microtubules running perpendicular to the lateral microtubules below the microvilli and also along the base of the cell (Figure 21-26b); how these arrangements are established is not known. Membrane traffic is also polarized (Figure 21-26c). Newly made membrane proteins destined for the apical and basolateral membranes are sorted and packaged into distinct transport vesicles at the *trans*-Golgi network (TGN) and then transported to the appropriate surface. In addition, endocytic pathways from both the apical and basolateral surfaces transport missorted proteins utilizing a complex set of sorting endosomes.

In genetic screens for additional components important for epithelial-cell polarity in the fly, components of endocytic trafficking were found. For example, one such mutant affects the trafficking of the apical transmembrane protein Crumbs, so that when endocytosis is compromised, the level of Crumbs on the surface goes up and the apical domain expands. Thus epithelial polarity involves responses to spatial cues and reorganization of the cytoskeleton that provides a framework for both secretory and endocytic membrane traffic pathways for establishment and maintenance of the polarized state.

The Planar Cell Polarity Pathway Orients Cells within an Epithelium

We have so far only discussed asymmetry in one dimension, but in many cases cells are polarized in at least two dimensions—top to bottom and front to back. Just by looking at features of

EXPERIMENTAL FIGURE 21-27 Planar-cell polarity (PCP) determines the orientation of cells. (a) On the wing of the fly, each cell produces a hair pointing in the same direction. The directionality is determined by the asymmetric localization of components of the CPC pathway, as indicated for Frizzled, Dishevelled, Flamingo, and Strabismus, all of which are needed for orienting the hair appropriately. In (b) examples of the distribution of hairs in a wild-type fly and the *Dishevelled* mutant are shown. Notice that in the mutant, the wing cells appear normal except the hairs are not correctly oriented. (c) The sensory hair cells of the vertebrate inner ear have V-shaped arrangements of stereocilia on their surface. In the adult and 18.5-day embryo, all the cells are oriented in precisely the same way. In a mouse *Crash* mutant (the vertebrate homolog of Flamingo) defective in PCP, the cells in the 18.5-day embryo appear normal, but their relative orientations are disrupted (arrows). [Parts (a) and (b) modified from J. D. Axelrod and C. J. Tomlin, 2011, *Wiley Interdisc. Revs. Sys. Biol. Med.* **3**:588–605; part (c) from M. Fanto et al., 2004, *J. Cell Sci.* **117**:527–553.]

the animals around us, such as the scales on fish, the feathers of birds, or the hairs on your arm, it is clear that the groups of cells that give rise to these structures must be organized in a front-to-back manner in addition to a top-to-bottom manner. This type of polarity is called *planar-cell polarity (PCP)*. A well-studied example from the fly is the single hair that points backward on each cell of the fly wing (Figure 21-27a). As we have seen, the fly is a system that is particularly amenable to genetic dissection. This analysis has shown that each cell responds to the

FIGURE 21-28 Two ways that stem cells can be induced to divide asymmetrically. (a) In response to an external cue, the cell polarizes and fate determinants (red dots) become segregated at cell division, leaving one stem cell and one differentiating cell. (b) Stem cells interacting in a stem-cell niche (red curved object) orient their mitotic spindle to give rise to a stem cell associated with the niche and a differentiating cell distant from it. [From S. J. Morrison and J. Kimble, 2006, *Nature* 441:1068–1074.]

planar direction of its neighbor, and components that specifically affect PCP have been identified. The overall planar polarity of an epithelium is probably determined by a gradient of some ligand. This gradient polarizes all the cells in the epithelium in the same manner, with one class of proteins, for example those encoded by the *Frizzled* and *Dishevelled* genes, on one side of each cell and a second group, for example those encoded by the *Flamingo* and *Strabismus* genes, on the other (Figure 21-27a). When components of the PCP pathway are disrupted, for example in a *Dishevelled* mutant, the epithelium is perfectly intact, but the hairs are misoriented (Figure 21-27b).

The complementary arrangement of PCP components means that the membrane protein *Strabismus* on the side of one cell will be adjacent to the *Frizzled* protein on the adjacent cell; indeed, these two proteins interact, and this interaction is probably important in coordinating PCP across an epithelium. This asymmetric distribution of PCP proteins leads, in an unknown manner, to the growth of the hair with the appropriate orientation. Although we have met *Frizzled* as a transmembrane receptor and *Dishevelled* as an adapter protein in the context of the Wnt pathway (see Figure 16-30), their role in the planar cell polarity pathway does not appear to involve Wnt but some other ligand.

Another clear example of planar-cell polarity is the sensory hair cells of the inner ear that allow you to perceive sounds. These cells have an ordered array of stereocilia arranged in a V-shaped pattern, and each cell is oriented precisely like its neighbor. In a mouse with a defect in the planar cell polarity gene *Crash* (the vertebrate homolog of fly *Flamingo*), the orderly arrangement of stereocilia within any given cell is preserved, but the relative orientations of cells to each other are disrupted (Figure 21-27c), and these types of defects can result in deafness.

The Par Proteins Are Also Involved in Asymmetric Cell Division of Stem Cells

We have seen that stem cells often give rise to a daughter stem cell and a differentiated cell. What are the cues that set up these asymmetric cell divisions? Two types of mechanisms have been found (Figure 21-28). In one mechanism, cell fate determinants are segregated to one end of the cell before cell

division, in response to external cues. This involves the apical Par proteins, which we have already seen are instrumental in the first asymmetric division of the nematode embryo and in establishing epithelial-cell polarity. In the second mechanism, the stem cell divides with a reproducible orientation so that it remains associated with the stem-cell niche, whereas the daughter is placed away from the niche and can then differentiate. This is the situation we have already encountered in the *Drosophila* ovary, where the cap cells form a niche for the germ-line stem cells (see Figure 21-9).

A particularly well-understood example of the asymmetric division of stem cells is the formation of neurons and glial cells in the central nervous system of the fly *Drosophila* (Figure 21-29). In this system, the neuroblast stem cell arises from the neurogenic ectoderm, which is a typical epithelial layer with apical and basal surfaces. The neuroblast cell enlarges (step 1) and moves basally into the interior of the embryo but remains in contact with the ectoderm epithelium (step 2). It now divides asymmetrically (step 3) to give rise to a new neuroblast stem cell and a ganglion mother cell (step 4). The ganglion mother cell can only divide once, giving rise to two cells, either nerve and/or glial cells. The neuroblast, being a stem cell by maintaining an association with the neurogenic ectoderm niche, can divide repeatedly, giving rise to many ganglion mother cells and hence neurons and glial cells (step 5) and so populates the central nervous system. Thus the key event is the ability of the neuroblast to divide asymmetrically (Figure 21-29b). Once again, this process involves the asymmetric accumulation of the apical Par complex—Par3, Par6, aPKC—and its positioning at the apical side of the cell (Figure 21-29c). Other factors are then positioned at the basal aspect of the cell, and the mitotic spindle is set up so that cell division segregates the polarity determinants. One of these basally localized determinants is called *Miranda*, a protein that associates with factors that control proliferation and differentiation (Figure 21-29c). Thus in the asymmetric division, *Miranda* and its associated

VIDEO: Mitotic Spindle Asymmetry in *Drosophila* Neuroblast-Cell Division

FIGURE 21-29 Neuroblasts divide asymmetrically to generate neurons and glial cells in the central nervous system. (a) Neuroblasts, which are stem cells, originate from the ectoderm by signals that induce them to enlarge **1**. They then move basally out of the epithelium but remain in contact with it **2**. Neuroblasts then undergo an asymmetric division **3** to give a neuroblast and a ganglion mother cell (GMC) **4**. The GMC then divides once to give two neurons or glial

cells **5**. Meanwhile, the neuroblast stem cell can divide many times to give more GMCs and so populate the neural tissue. (b) The asymmetric division of the neuroblast requires the correct orientation of the mitotic spindle to give rise to a larger neuroblast and a smaller GMC cell. (c) A neuroblast at anaphase showing the segregated localization of the apical Par proteins (green) and the basal Miranda protein (red). [Part (c) from C. Cabernard and C. Q. Doe, 2009, *Dev. Cell* **17**:134–141.]

factors are segregated away from the neuroblast stem cell and into the ganglion mother cell.

KEY CONCEPTS of Section 21.3

Mechanisms of Cell Polarity and Asymmetric Cell Division

- Cell polarity involves the asymmetric distribution of proteins, lipids, and other macromolecules in the cell.
- Asymmetry requires cells to sense a cue, respond to it by assembling a polarized cytoskeleton, and then using this polarity to distribute factors appropriately.
- Asymmetric cell division requires cells to first become polarized, followed by division to segregate fate determinants asymmetrically.
- Mating in haploid yeast involves assembly of a mating projection (shmoo) by polarizing the cytoskeleton in the direction of highest concentration of mating pheromone and targeting secretion of cellular components for cell expansion there.

- Anterior/posterior asymmetry in the first division of the nematode worm embryo involves asymmetric F-actin/myosin-II contraction to localize the cortical anterior Par3, Par6, aPKC complex followed by the cortical association of posterior factors such as Par2.
- Apical/basal epithelial-cell polarity is also driven by the apical Par3, Par6, aPKC complex, which functions in antagonistic relationships with the apical Crumbs complex and the basal Scribble complex.
- Planar-cell polarity regulates the relative orientation of cells in a sheet.
- Asymmetric division of stem cells often involves association of the stem cell with a niche, giving rise to another stem cell and a differentiating cell.
- Asymmetric stem-cell division also involves the asymmetric distribution of the Par3, Par6, aPKC complex, which is retained in the stem cell during division, whereas fate determinants are localized away from the Par complex to end up in the differentiating cell.

21.4 Cell Death and Its Regulation

Programmed cell death is a counterintuitive, but essential, cell fate. During embryogenesis, death of specific cells keeps our hands from being webbed, our embryonic tails from persisting, and our brain from being filled with useless nerve connections. In fact, the majority of cells generated during brain development subsequently die. We will see in Chapter 23 how immune cells that react to normal body proteins or that produce nonfunctional antibodies are selectively killed. Many outworn muscle, epithelial, and white blood cells constantly die and need to be replaced.

Cellular interactions regulate cell death in two fundamentally different ways. First, most if not all cells in multicellular organisms require specific protein hormone signals to stay alive. In the absence of such survival signals, fre-

quently referred to as **trophic factors**, cells activate a “suicide” program. Second, in some developmental contexts, including the immune system, other specific hormone signals induce a “murder” program that kills cells. Whether cells commit suicide for lack of survival signals or are murdered by killing signals from other cells, death is mediated by a common molecular pathway. In this section, we first distinguish programmed cell death from death due to tissue injury and then describe how genetic studies in the worm *C. elegans* led to elucidation of an evolutionarily conserved effector pathway that leads to cell suicide or murder. We then turn to vertebrates, where cell death is regulated both by trophic factors, as exemplified by their importance in programmed cell death in neuronal development, and cell stresses such as DNA damage. Finally we illustrate the key roles of mitochondria in initiating the cell death pathway.

VIDEO: Cells Undergoing Apoptosis

FIGURE 21-30 Ultrastructural features of cell death by apoptosis.

(a) Schematic drawings illustrating the progression of morphologic changes observed in apoptotic cells. Early in apoptosis, dense chromosome condensation occurs along the nuclear periphery. The cell body also shrinks, although most organelles remain intact. Later both the nucleus and cytoplasm fragment, forming apoptotic bodies, which are phagocytosed by surrounding cells. (b) Photomicrographs comparing a normal cell (top) and apoptotic cell (bottom). Clearly visible in the latter are dense spheres of compacted chromatin as the nucleus begins to fragment. [Part (a) adapted from J. Kuby, 1997, *Immunology*, 3d ed., W. H. Freeman and Co., p. 53; part (b) from M. J. Arends and A. H. Wyllie, 1991, *Int'l. Rev. Exp. Pathol.* 32:223.]

FIGURE 21-31 Newly hatched larva of *C. elegans*. Some of the 959 somatic-cell nuclei in the hermaphrodite form are visualized in this micrograph obtained by differential interference contrast (DIC)

microscopy, sometimes called Nomarski microscopy. The most easily seen are the intestinal nuclei, which appear as round disks. [From J. E. Sulston and H. R. Horvitz, 1977, *Devel. Biol.* **56**:110.]

Programmed Cell Death Occurs Through Apoptosis

The demise of cells by programmed cell death is marked by a well-defined sequence of morphological changes, collectively referred to as **apoptosis**, a Greek word that means “dropping off” or “falling off,” as leaves from a tree. Dying cells shrink, condense, and then fragment, releasing small membrane-bound apoptotic bodies, which generally are then engulfed by other cells (Figure 21-30). In dying cells, nuclei condense and the DNA is fragmented. Importantly, the intracellular constituents are not released into the extracellular milieu, where they might have deleterious effects on neighboring cells. The stereotypical changes that occur in cells during apoptosis, such as condensation of the nucleus and engulfment by surrounding cells, suggested to early scientists that this type of cell death was under the control of a strict program. This program is critical during both embryonic and adult life to maintain normal cell number and composition.

The genes involved in controlling cell death encode proteins with three distinct functions:

- “Killer” proteins are required for a cell to begin the apoptotic process.
- “Destruction” proteins do things such as digest DNA in a dying cell.
- “Engulfment” proteins are required for phagocytosis of the dying cell by another cell.

At first glance, engulfment seems to be simply an after-death cleanup process, but some evidence suggests that it is part of the final death process. For example, mutations in killer genes always prevent cells from initiating apoptosis, whereas mutations that block engulfment sometimes allow cells to persist for a while before dying. Engulfment involves the assembly of a halo of actin in the engulfing cell around the dying cell, triggered by apoptosis proteins that activate Rac, a monomeric G protein that helps regulate actin polymerization (see Figure 17-44). A signal on the surface of the

dying cell also stimulates a receptor on neighboring cells, which initiates membrane changes leading to engulfment.

In contrast to apoptosis, cells that die in response to tissue damage exhibit very different morphological changes, referred to as **necrosis**. Typically, cells that undergo this process swell and burst, releasing their intracellular contents, which can damage surrounding cells and frequently causes inflammation.

Evolutionarily Conserved Proteins Participate in the Apoptotic Pathway

The confluence of genetic studies in *C. elegans* and studies on human cancer cells suggested that an evolutionarily conserved pathway mediates apoptosis. In *C. elegans*, cell lineages are under tight genetic control and are identical in all individuals of a species. About 10 rounds of cell division or fewer create the adult worm, which is about 1 mm long and 70 μm in diameter. The adult worm has 959 somatic-cell nuclei (hermaphrodite form) or 1031 (male) (Figure 21-31). Scientists have traced the lineage of all the 947 somatic cells in *C. elegans* from the fertilized egg to the mature worm by following the development of live worms using Nomarski differential interference contrast (DIC) microscopy (see Figure 21-23c). The number of somatic cells is somewhat fewer than the number of nuclei because some cells contain multiple nuclei; that is, they are syncytial. From the zygote a series of asymmetric cell divisions produce founder cells that in turn generate all of the differentiated cells.

Of the 947 nongonadal cells generated during development of the adult hermaphrodite form, 131 undergo programmed cell death. Specific mutations have identified four genes whose encoded proteins play an essential role in controlling programmed cell death during *C. elegans* development: *ced-3*, *ced-4*, *ced-9*, and *egl-1*. In *ced-3* or *ced-4* mutants, for example, the 131 “doomed” cells survive (Figure 21-32). These mutants formed the first pieces of evidence that apoptosis was under a genetic program. The mammalian proteins that correspond most closely to the worm CED-3, CED-4, CED-9, and EGL-1 proteins are indicated in

EXPERIMENTAL FIGURE 21-32 Mutations in the *ced-3* gene block programmed cell death in *C. elegans*. (a) Newly hatched mutant larva carry a mutation in the *ced-1* gene. Because mutations in this gene prevent engulfment of dead cells, highly refractile dead cells accumulate (arrows), facilitating their visualization. (b) Newly hatched larva with

mutations in both the *ced-1* and *ced-3* genes. The absence of refractile dead cells in these double mutants indicates that no cell deaths occurred. Thus the CED-3 protein is required for programmed cell death. [From H. M. Ellis and H. R. Horvitz, 1986, *Cell* 91:818; courtesy of Hilary Ellis.]

Figure 21-33. In discussing the worm proteins, we will include the mammalian names in parentheses to make it easier to keep the relationships clear.

The first mammalian apoptotic gene to be cloned, *bcl-2*, was isolated from human follicular lymphomas. A mutant form of this gene was created in lymphoma cells; a chromosomal rearrangement joined the protein-coding region of the *bcl-2* gene to an immunoglobulin gene enhancer. The combination results in overproduction of the Bcl-2 protein that keeps these cancer cells alive when otherwise they would become programmed to die. The human Bcl-2 protein and worm CED-9 protein are homologous; even though the two proteins are only 23 percent identical in sequence, a *bcl-2* transgene can block the

extensive cell death found in *ced-9* mutant worms. Thus both proteins act as regulators that suppress the apoptotic pathway (Figure 21-33). In addition, both proteins contain a single transmembrane domain and are localized mainly to the outer mitochondrial membrane, where they serve as sensors that

FIGURE 21-33 Evolutionary conservation of apoptosis pathways. Similar proteins, shown in identical colors, play corresponding roles in both nematodes and mammals. (a) In nematodes, the BH3-only protein called EGL-1 binds to CED-9 on the surface of mitochondria; this interaction releases CED-4 from the CED-4/CED-9 complex. Free CED-4 then binds to and activates by autoproteolysis the caspase CED-3, which destroys cell proteins to drive apoptosis. These relationships are shown as a genetic pathway, with EGL-1 inhibiting CED-9, which in turn inhibits CED-4. Active CED-4 activates CED-3. (b) In mammals, homologs of the nematode proteins as well as many other proteins not found in worms regulate apoptosis. The Bcl-2 protein is similar to CED-9 in promoting cell survival. It does so in part by preventing activation of Apaf-1, which is similar to CED-4, and in part by other mechanisms depicted in Figure 21-38. Several types of BH3-only proteins, also detailed in Figures 21-37 and 21-38, inhibit Bcl-2 and thus allow apoptosis to proceed. Apoptotic stimuli damage mitochondria, leading to release of several proteins that stimulate cell death. In particular, cytochrome c released from mitochondria activates Apaf-1, which in turn activates caspase-9. This initiator caspase then activates effector caspases -3 and -7, eventually leading to cell death. See text for discussion of other mammalian proteins (SMAC/DIABLO and IAPs) that have no nematode homologs. [Adapted from S. J. Riedl and Y. Shi, 2004, *Nat. Rev. Mol. Cell Biol.* 5:897.]

FIGURE 21-34 Activation of CED-3 protease in *C. elegans*. EGL-1 protein, which is produced in response to developmental signals that trigger cell death, displaces an asymmetric CED-4 dimer from its association with CED-9 on the surface of mitochondria **1**. The free CED-4 dimer combines with three others to form an octamer **2**, which binds two

molecules of the CED-3 zymogen (an enzymatically inactive precursor of a protease) and triggers the conversion of the CED-3 zymogens into active CED-3 protease **3**. This effector caspase then begins to destroy cell components and thus initiate apoptosis, leading to cell death **4**. [Adapted from N. Yan et al., 2005, *Nature* **437**:831, and S. Qi et al., 2010, *Cell* **141**:446.]

control the apoptotic pathway in response to external stimuli. As we discuss next, other regulators promote apoptosis.

In the worm apoptotic pathway, CED-3 (caspase-9 in mammals) is required to destroy cell components during apoptosis. CED-4 (Apaf-1) is a protease-activating factor that causes autocleavage of (and by) the CED-3 precursor protein, creating an active CED-3 (caspase-9) protease that initiates cell death (Figures 21-33 and 21-34). Cell death does not occur in *ced-3* and *ced-4* single mutants or in *ced-9/ced-3* double mutants, whereas all cells die during embryonic life in *ced-9* mutants, so the adult form never develops. These genetic studies indicate that CED-3 and CED-4 are “killer” proteins required for cell death, that CED-9 (Bcl-2) suppresses apoptosis, and that the apoptotic pathway can be activated in all cells. Moreover, the absence of cell death in *ced-9/ced-3* double mutants suggests that CED-9 acts “upstream” of CED-3 to suppress the apoptotic pathway.

The mechanism by which CED-9 (Bcl-2) controls CED-3 (caspase-9) is now known. CED-9 protein, which is normally tethered to the outside of mitochondria, forms a complex with an asymmetric CED-4 (Apaf-1) dimer, thereby preventing activation of CED-3 by CED-4 (Figure 21-34). As a result, the cell survives. This mechanism fits with the genetics, which shows that the absence of CED-9 has no effect if CED-3 is also missing (*ced-3/ced-9* double mutants have no cell death). The three-dimensional structure of the trimeric CED-4/CED-9 complex reveals a huge contact surface between each of the two CED-4 molecules and the single CED-9 molecule; the large contact surface makes the association highly specific, but in such a way that the dissociation of the complex can be regulated.

Transcription of *egl-1*, the fourth genetically defined apoptosis regulator gene, is stimulated in *C. elegans* cells that are programmed to die, but how this is regulated is not yet clear. Newly produced EGL-1 protein binds to CED-9, alters its conformation, and catalyzes the release of CED-4 from it (Figure 21-34). Both EGL-1 and CED-9 contain a 12-amino-acid BH3 domain. Since EGL-1 lacks most of the other domains of CED-9, EGL-1 is called a *BH3-only protein*. The closest mammalian BH3-only proteins are the proapoptotic Bim and Bid.

Insight into how EGL-1 disrupts the CED-4/CED-9 complex comes from the molecular structure of EGL-1 (Bid/Bim) complexed with CED-9 (Bcl-2). In this complex, the BH3 domain forms the key part of the contact surface between the two proteins. CED-9 has a different conformation when bound by EGL-1 than when bound by CED-4. This finding suggests that EGL-1 binding distorts CED-9, making its interaction with CED-4 less stable. Once EGL-1 causes dissociation of the CED-4/CED-9 complex, the released CED-4 dimer joins with three other CED-4 dimers to make an octamer, which then activates CED-3 by a mechanism discussed later. Cell death soon follows (Figure 21-34).

Evidence that the steps described here are sufficient to induce apoptosis comes from experiments in which the events were reconstituted in vitro with purified proteins. CED-3, CED-4, a truncated CED-9 that lacked its transmembrane mitochondrial membrane anchor, and EGL-1 were purified, as was a CED-4/CED-9 complex. Purified CED-4 (Apaf-1) was able to accelerate the autocatalysis of purified CED-3 (caspase-9), but addition of the truncated CED-9 (Bcl-2) to the reaction mixture inhibited the autocleavage. When the CED-4/CED-9 complex was mixed with CED-3, autocleavage did *not* occur, but addition of EGL-1 to the reaction restored CED-3 autocleavage.

Caspases Amplify the Initial Apoptotic Signal and Destroy Key Cellular Proteins

The effector proteins in the apoptotic pathway, the **caspases**, are named because they contain a key *cysteine* residue in the catalytic site and selectively cleave proteins at sites just C-terminal to *aspartate* residues. Caspases work as homodimers, with one domain of each stabilizing the active site of the other. The principal effector caspase in *C. elegans* is CED-3, while humans have 15 different caspases. All caspases are initially made as procaspases that must be cleaved to become active. In vertebrates, initiator caspases (e.g., caspase-9) are activated by dimerization induced by binding to other types of proteins

(e.g., Apaf-1), which help the initiators to aggregate. Activated initiator caspases cleave effector caspases (e.g., caspase-3) to activate them; in this way the proteolytic activity of the few activated initiator caspases becomes rapidly and hugely increased by activation of the effector caspases, leading to a massive increase in the total caspase activity level in the cell (see Figure 21-33) and cell death. Procaspases preexist in large enough numbers to accomplish the digestion of much of the cellular protein when activated by the small number of molecules that constitute the initiation signal. The various effector caspases recognize and cleave short amino acid sequences in many different target proteins. They differ in their preferred target sequences. Their specific intracellular targets include proteins of the nuclear lamina and cytoskeleton whose cleavage leads to the demise of a cell.

Neurotrophins Promote Survival of Neurons

In mammals, but not worms, apoptosis is regulated by intracellular signals generated from many secreted and cell-surface protein hormones, as well as by many environmental stresses, such as ultraviolet irradiation and DNA damage. While the “core” apoptosis machinery in *C. elegans* is conserved in mammals, many other intracellular proteins also regulate apoptosis (see Figure 21-33, right).

But before plunging into these molecular details, we’ll illustrate the importance of trophic factors in apoptosis by a brief analysis of the developing nervous system. When neurons grow to make connections to other neurons or to muscles, sometimes over considerable distances, more neurons grow than will eventually survive. Cell bodies of many sensory and motor neurons are located in the spinal cord and adjacent ganglia, while their long axon processes extend far outside these regions. Those that make connections prevail and survive; those that fail to connect will die.

In the early 1900s the number of neurons innervating peripheral cells was shown to depend on the size of the tissue to which they would connect, the so-called target field. For instance, removal of limb buds from the developing chick embryo leads to a reduction in the number of sensory neurons and also motor neurons innervating muscles in the bud (Figure 21-35). Conversely, grafting additional limb tissue to a limb bud leads to an increased number of neurons in corresponding regions of the spinal cord and sensory ganglia. Indeed, incremental increases in the target-field size are accompanied by commensurate incremental increases in the number of neurons innervating the target field. This relationship was found to result from the selective survival of neurons rather than changes in their differentiation or proliferation. The observation that many sensory and motor neurons die after reaching their peripheral target field suggested that these neurons compete for survival factors produced by the target tissue.

Subsequent to these early observations, scientists discovered that transplantation of a mouse sarcoma (muscle tumor) into a chick led to a marked increase in the local numbers of certain types of neurons. This finding implicated the tumor as a rich source of the presumed trophic factor. To isolate and

purify this factor, known simply as nerve growth factor (NGF), scientists used an in vitro assay in which outgrowth of neurites from sensory ganglia (nerves) was measured. Neurites are extensions of the cell cytoplasm that can grow to become the long wires of the nervous system, the axons and dendrites (see Figure 22-1). The later discovery that the submaxillary gland in the mouse also produces large quantities of NGF enabled biochemists to purify and to sequence it. A homodimer of two 118-residue polypeptides, NGF belongs to a family of structurally and functionally related trophic factors collectively referred to as neurotrophins. Brain-derived neuro-

EXPERIMENTAL FIGURE 21-35 In vertebrates the survival of motor neurons depends on the size of the muscle target field they innervate. (a) Removal of a limb bud from one side of a chick embryo at about 2.5 days results in a marked decrease in the number of motor neurons on the affected side. In an amputated embryo (top), normal numbers of motor neurons are generated on both sides (middle). Later in development, many fewer motor neurons remain on the side of the spinal cord with the missing limb than on the normal side (bottom). Note that normally only about 50 percent of the motor neurons that originally are generated survive. (b) Transplantation of an extra limb bud into an early chick embryo produces the opposite effect, more motor neurons on the side with additional target tissue than on the normal side. [Adapted from D. Purves, 1988, *Body and Brain: A Trophic Theory of Neural Connections*, Harvard University Press, and E. R. Kandel, J. H. Schwartz, and T. M. Jessell, 2000, *Principles of Neural Science*, 4th ed., McGraw-Hill, p. 1054, Figure 53-11.]

EXPERIMENTAL FIGURE 21-36 Different classes of sensory neurons are lost in knockout mice lacking different trophic factors or their receptors. In animals lacking nerve growth factor (NGF) or its receptor TrkA, small nociceptive (pain-sensing) neurons (light blue) that innervate the skin are missing. These neurons express TrkA receptor and innervate NGF-producing targets. In animals lacking either neurotrophin-3 (NT-3) or its receptor TrkC, large proprioceptive neurons (red) innervating muscle spindles are missing. Muscle produces NT-3, and the proprioceptive neurons express TrkC. Mechanoreceptors (orange; see Figure 22-24), another class of sensory neurons in the dorsal root ganglion, are unaffected in these mutants. [Adapted from W. D. Snider, 1994, *Cell* 77:627.]

trophic factor (BDNF) and neurotrophin-3 (NT-3) are members of this protein family.

Neurotrophins bind to and activate a family of receptor tyrosine kinases called *Trks* (pronounced “tracks”). (The general structure of receptor tyrosine kinases and the intracellular signaling pathways they activate are covered in Chapter 16.) Each neurotrophin binds with high affinity to one Trk receptor: NGF binds to TrkA; BDNF, to TrkB; and NT-3, to TrkC. NT-3 can also bind with lower affinity to both TrkA and TrkB. These bindings—between factors and their receptors—provide a survival signal for different classes of neurons. As neurons grow from the spinal cord to the periphery, neurotrophins produced by target tissues bind to Trk receptors on the growth cones (see Figure 18-52) of the extending axons, promoting survival of neurons that successfully reach targets. In addition, neurotrophins bind to a distinct type of receptor called p75^{NTR} (NTR 5 neurotrophin receptor) but with lower affinity. However, p75^{NTR} forms heteromultimeric complexes with the different Trk receptors; this association increases the affinity of Trks for their ligands. Depending on the cell type, binding of NGF and BDNF to p75^{NTR} in the absence of TrkA may promote cell death rather than prevent it. (The phenomenon of multiple neurotrophins interacting with multiple similar receptors is comparable to EGF-like ligands and their HER receptors, illustrated in Figure 16-7).

To critically address the role of neurotrophins in development, scientists produced mice with knockout mutations in each of the neurotrophins and their receptors. These studies revealed that different neurotrophins and their corresponding receptors are required for the survival of different classes of sensory neurons (Figure 21-36). For instance, pain-sensitive (nociceptive) neurons, which express TrkA, are selectively lost from the dorsal root ganglion of knockout mice lacking NGF or TrkA, whereas TrkB- and TrkC-expressing neurons are unaffected in such knockouts. In contrast, TrkC-expressing proprioceptive neurons, which detect the position of the limbs, are missing from the dorsal root ganglion in *TrkC* and *NT-3* mutants.

Mitochondria Play a Central Role in Regulation of Apoptosis in Vertebrate Cells

As discussed previously, *C. elegans* CED-9 and its mammalian homolog Bcl-2 play central roles in repressing apoptosis. In nematodes, CED-9 does so by binding to and repressing the activation of CED4. In vertebrates, Bcl-2, residing in the outer mitochondrial membrane, primarily functions to maintain the low permeability of that membrane, preventing cytochrome *c* and other proteins localized to the intermembrane space (see Figure 12-16) from diffusing into the cytosol and activating apoptotic caspases.

In order to explain how Bcl-2 carries out this function and how Bcl-2 activity is regulated by trophic factors and by many environmental stimuli, we need to introduce several other important members of the *Bcl-2* family of proteins. All members of the Bcl-2 family share a close homology in up to four characteristic regions termed the *Bcl-2* homology domains (BH1–4 domains; Figure 21-37). Each protein has

FIGURE 21-37 Bcl-2 family proteins. The Bcl-2 family is made of proteins that contain functional Bcl homology domains (BH 1–4) and are divided into three classes. Only some of the BH3-only proteins contain transmembrane (TM) domains. [After M. Giam et al., 2009, *Oncogene* 27:S128.]

FIGURE 21-38 Integration of multiple signaling pathways in vertebrate cells that regulate mitochondrial outer membrane permeability and apoptosis. In healthy cells the anti-apoptotic protein Bcl-2 or its homolog Bcl-xL binds to the Bak and Bax BH3-only proteins in the outer mitochondrial membrane, blocking the ability of Bak and Bax to oligomerize and form oligomeric channels. Binding of certain BH3-only proteins, including Bim and Puma, directly to Bak and Bax causes them to form oligomeric channels in the outer mitochondrial membrane. This allows cytochrome c to enter the cytosol, where it binds to the adapter protein Apaf-1, promoting caspase activation that initiates the apoptotic cascade and leads to cell death. Other BH3-only proteins, including Bad, bind to Bcl-2, blocking its ability to bind to Bak and Bax and causing them to form channels in the outer mitochondrial membrane. Several stimuli trigger or repress this apoptotic pathway.

(1) The presence of specific trophic factors (e.g., NGF) leads to activation of the cognate receptor protein tyrosine kinase (e.g., TrkA) and activation of the PI-3 kinase PKB (protein kinase B; also called Akt) pathway (see Figure 16-26). PKB phosphorylates Bad, and phosphorylated Bad then forms a complex with the 14-3-3 protein. With Bad sequestered, it is unable to bind to Bcl-2. In the absence of trophic factors, unphosphorylated Bad binds to Bcl-2, releasing Bax and Bak and allowing them to form the oligomeric channel. (2) DNA damage or ultraviolet irradiation leads to induction of the BH3-only Puma protein. Puma binds to Bax and Bak, allowing them to form oligomeric channels. (3) Removal of a cell from its substratum disrupts integrin signaling, leading to release of the BH3-only Bim protein from the cytoskeleton. Bim also binds to Bax and Bak to promote channel formation. [After D. Ren et al., 2010, *Science* 330:1390.]

either a pro-survival or a pro-apoptotic function. Many members of this family are single-pass transmembrane proteins and all participate in oligomeric interactions.

The Pro-apoptotic Proteins Bax and Bak Form Pores in the Outer Mitochondrial Membrane

In vertebrate cells, Bax or Bak is required for mitochondrial damage and induction of apoptosis. These two similar pro-apoptotic proteins contain several of the BH1–4 domains (see Figure 21-37) and have a three-dimensional structure very similar to that of the pro-survival members of the family. As evidence for their role in promoting apoptosis, most mice lacking both Bax and Bak die *in utero*. Those that survive show significant developmental defects, including the persistence of interdigital webs and accumulation of extra cells in the central nervous and hematopoietic systems. Cells isolated from these mice are resistant to virtually all apoptotic stimuli. Conversely, overproduction of Bax in cultured cells induces death.

Bax and Bak reside in the outer mitochondrial membrane, normally tightly bound to Bcl-2 (Figure 21-38). When released from Bcl-2—either by being present in excess, by being displaced by binding of certain BH3-only proteins to Bcl-2, or by direct binding to other BH3-only proteins—Bax and Bak form oligomers that generate pores in the outer mitochondrial membrane. This allows release into the cytosol of mitochondrial proteins such as cytochrome *c* that, in normal healthy cells, are localized in the space between the inner and outer mitochondrial membrane. As depicted in Figure 21-33, released cytochrome *c* activates caspase-9—in part through binding to and activating Apaf-1 and in part through as yet unknown mechanisms.

As evidence for this regulatory pathway, overproduction of Bcl-2 in cultured cells blocks release of cytochrome *c* and blocks apoptosis; conversely, overproduction of Bax promotes release of cytochrome *c* into the cytosol and promotes apoptosis. Moreover, injection of cytochrome *c* into the cytosol of cells induces apoptosis. Bax and Bak oligomers, but not Bcl-2 homodimers or Bcl-2/Bax heterodimers, permit influx of ions through the outer mitochondrial membrane. It remains unclear how this ion influx triggers the release of cytochrome *c*, and it is not established whether cytochrome *c* actually moves outward through Bax/ Bak channels.

Release of Cytochrome *c* and SMAC/DIABLO Proteins from Mitochondria Leads to Formation of the Apoptosome and Caspase Activation

The principal way cytochrome *c* in the cytosol activates apoptosis is by binding Apaf-1, the mammalian homolog of CED-4 (see Figure 21-33, *right*). In the absence of cytochrome *c*, monomeric Apaf-1 is bound to dATP. After binding cytochrome *c*, Apaf-1 cleaves its bound dATP into dADP and undergoes a dramatic assembly process into a disk-shaped heptamer, a 1.4-megadalton wheel of death called

the **apoptosome** (Figure 21-39). The apoptosome serves as an activation machine for the initiator caspase, caspase-9, which is monomeric in the inactive state. Initiator caspases need to be sensitive to activation signals yet should not be activatable in an irreversible manner because accidental activation would lead to an undesirable snowball effect and rapid cell death. Significantly, caspase-9 does not require cleavage to become activated, but rather it is activated by dimerization following binding to the apoptosome. Caspase-9 then cleaves multiple molecules of effector caspases, such as caspase-3, leading to destruction of cell proteins (see Figures 21-33 and 21-38).

The three-dimensional structure of the corresponding nematode CED-4 apoptosome (see Figure 21-39c) showed how two CED-3 (caspase-9) procaspases bind adjacent to each other on the inside of the funnel-shaped octamer; these then activate each other by dimerization and proteolytic conversion, but the detailed mechanism of how this happens is unknown. The structure of the CED4 apoptosome also provided a model for the as yet unknown three-dimensional structure of the corresponding mammalian apoptosome (see Figure 21-39b, *right*).

In mammals and flies, but not worms, apoptosis is regulated by several other proteins (see Figure 21-33, *right*). A family of **inhibitor of apoptosis proteins** (IAPs) provides another way to restrain both initiator and effector caspases. IAPs have one or more zinc-binding domains that can bind directly to caspases and inhibit their protease activity. (Baculovirus, a type of insect virus, produces a protein that similarly binds to and inhibits caspases, thus preventing an infected cell from committing suicide which would stop a viral infection before new viruses can be made.) The inhibition of caspases by IAPs, however, creates a problem when a cell needs to undergo apoptosis. Mitochondria enter the picture once again since they are the source of a family of proteins, called **SMAC/DIABLOs**, which inhibit IAPs. Assembly of Bax/Bak channels (see Figure 21-38) leads to release of SMAC/DIABLOs from mitochondria. SMAC/DIABLO then binds to IAPs in the cytosol, thereby blocking the IAPs from binding to caspases. By relieving IAP-mediated inhibition, SMAC/DIABLOs promote caspase activity and cell death.

Trophic Factors Induce Inactivation of Bad, a Pro-apoptotic BH3-Only Protein

We saw earlier that neurotrophins such as nerve growth factor protect neurons from cell death; this is mediated by the BH3-only protein called Bad. In the absence of trophic factors, Bad is unphosphorylated and binds to Bcl-2 or the closely related anti-apoptotic protein Bcl-xL at the mitochondrial membrane (see Figure 21-38). This inhibits the ability of Bcl-2 and Bcl-xL to bind Bax and Bak, thereby allowing Bak and Bax channels to form and promoting cell death. Phosphorylated Bad, however, cannot bind to Bcl-2/Bcl-xL and is found in the cytosol complexed to the phosphoserine-binding protein 14-3-3 (see Figure 16-20).

FIGURE 21-39 Structure of the nematode apoptosome and a model for the structure of the mammalian Apaf1 apoptosome. (a) Domains of the CED-4 protein and the corresponding mammalian Apaf1; CARD stands for N-terminal caspase recruitment domain. In the oligomeric apoptosome these CARD domains bind to CARD domains in the caspases. (b) Diagram of the CED4 apoptosome (*left*) and a model for the corresponding mammalian apoptosome (*right*). (c) Three-dimensional structure of the nematode octameric CED-4 apoptosome showing the binding of two CED-3 procaspases. Interaction of the apoptosome with CED-3 stimulates CED-3 dimerization, which is necessary for its activation. [From S. Qi et al., 2010, *Cell* 141:446.]

A number of trophic factors, including NGF, induce the PI-3 kinase signaling pathway, leading to activation of protein kinase B (see Figure 16-26). Activated protein kinase B phosphorylates Bad at sites known to inhibit its pro-apoptotic activity. Moreover, a constitutively active form of protein kinase B can rescue cultured neurotrophin-deprived neurons, which otherwise would undergo apoptosis and die. These findings support the mechanism for the survival action of trophic factors depicted in Figure 21-38. In other cell types, different trophic factors may promote cell survival through post-translational modification of other components of the cell-death machinery.

Vertebrate Apoptosis Is Regulated by BH3-Only Pro-Apoptotic Proteins That Are Activated by Environmental Stresses

Whereas worms contain a single BH3-only protein, Egl-1, mammals express at least eight, including Bad, in a cell and stress-specific manner. Their pro-apoptotic activity is regulated by diverse transcriptional and post-transcriptional mechanisms. Two, Puma and Noxa (see Figure 21-37), are transcriptionally induced by the p53 protein (see Figure 19-33); this is part of the checkpoint by which unrepaired damage to

DNA can induce apoptosis. Bim, on the other hand, is normally sequestered by the microtubule cytoskeleton by binding to a dynein light chain (see Figure 18-23). Detachment of cells from their substratum disrupts integrin signaling, rearranges the cytoskeleton, and leads to release of Bim. Both Puma and Bim likely bind directly to Bak and Bax, somehow releasing them from Bcl-2 and allowing formation of the oligomeric Bak/Bax pore and apoptosis (see Figure 21-38). Thus apoptosis of mammalian cells is regulated by a careful balance of activities of anti-apoptotic proteins such as Bcl-2 and Bcl-xL and multiple pro-apoptotic BH3-only proteins.

FIGURE 21-40 Cell murder: the extrinsic apoptosis pathway. In this example of an extrinsic (or death-receptor-regulated) pathway found in the immune system, binding of the Fas ligand FasL (also called CD95 ligand) on the surface of one cell to the death receptor Fas on an adjacent cell leads to recruitment of the adapter protein FADD (FAS-associated death domain) and the dimerization and activation of caspase-8. Active caspase-8 then cleaves and activates caspase-3, caspase-6, and caspase-7, which then cleave vital cellular substrates and induce cell death. Cleavage of the BH3-only protein BID (BH3-interacting-domain death agonist) by caspase-8 generates a t-BID fragment that binds to Bcl-2 on the mitochondrial outer membrane, leading to release of cytochrome *c* into the cytosol and activation of the intrinsic apoptosis pathway (see Figure 21-38) as well. [Adapted from P. Bouillet and L. O'Reilly, 2009, *Nat. Rev. Immunol.* 9:514.]

Tumor Necrosis Factor and Related Death Signals Promote Cell Murder by Activating Caspases

Although cell death can arise as a default in the absence of survival factors, apoptosis can also be stimulated by positively acting *death signals*. For instance, tumor necrosis factor alpha (TNF α), which is released by macrophages, triggers the cell death and tissue destruction seen in certain chronic inflammatory diseases (see Chapter 23). Another important death-inducing signal, the Fas ligand, is a cell-surface protein produced by activated natural killer cells and cytotoxic T lymphocytes. This signal can trigger death of virus-infected cells, some tumor cells, and foreign graft cells.

Both TNF α and Fas ligand (also called CD95 ligand), depicted in Figure 21-40, are proteins present on the surface of one cell that bind to death receptors on an adjacent cell. These receptors have a single transmembrane domain and are activated when binding of an oligomeric ligand brings three receptor molecules into close proximity. The activated trimeric Fas receptor complex then binds a cytosolic protein called FADD (Fas-associated death domain) to the cell membrane, which then serves as an adapter to recruit and activate caspase-8, an initiator caspase. Like the other initiator caspase, caspase-9, caspase-8 is activated by dimerization following binding of two molecules to the FADD proteins recruited to an active receptor trimer. Once activated, caspase-8 activates several effector caspases and the amplification cascade begins.

Caspase-8 also cleaves the BH3-only protein BH3-interacting-domain death agonist (BID). The resulting t-BID fragment then binds to Bcl-2 on the mitochondrial outer membrane, leading to formation of a Bak/Bax channel, release of cytochrome *c* into the cytosol, and activation of the intrinsic apoptosis pathway (see Figure 21-38) as well.

To test the ability of the Fas receptor to induce cell death, researchers incubated cells with antibodies against the receptor. These antibodies, which bind and cross-link the cognate receptors, were found to stimulate cell death, indicating that activation of these receptors by oligomerization is sufficient to trigger apoptosis.

KEY CONCEPTS of Section 21.4

Cell Death and Its Regulation

- All cells require trophic factors to prevent apoptosis and thus survive. In the absence of these factors, cells commit suicide.
- Genetic studies in *C. elegans* defined an evolutionarily conserved apoptotic pathway with three major components: membrane-bound regulatory proteins, cytosolic regulatory proteins, and effector proteases called caspases in vertebrates (see Figure 21-33).
- Once activated, apoptotic proteases cleave specific intracellular substrates leading to the demise of a cell. Proteins

(e.g., CED-4, Apaf-1) that bind regulatory proteins and caspases are required for caspase activation (see Figures 21-33, 21-34, and 21-39).

- Survival of motor and sensory neurons during development is mediated by neurotrophins released from target tissues that bind to Trk protein kinase receptors on the nerve growth cones (see Figure 21-36), activating an anti-apoptotic response via the PI-3 kinase pathway (see Figure 21-38).
- The Bcl-2 family contains both pro-apoptotic and anti-apoptotic proteins; most are single-pass transmembrane proteins and engage in protein-protein interactions.
- In mammals apoptosis can be triggered by oligomerization of Bax or Bak proteins in the outer mitochondrial membrane, leading to efflux of cytochrome *c* and SMAC/DIABLO proteins into the cytosol; these then promote caspase activation and cell death.
- Bcl-2 molecules can restrain the oligomerization of Bax and Bak, inhibiting cell death.
- Pro-apoptotic BH3-only proteins (e.g., Puma, Bad) are activated by environmental stress and stimulate the oligomerization of Bax and Bak, allowing cytochrome *c* to escape into the cytosol, bind to Apaf-1, and thus activate caspases.
- Direct interactions between pro-apoptotic and anti-apoptotic proteins lead to cell death in the absence of trophic factors. Binding of extracellular trophic factors can trigger changes in these interactions, resulting in cell survival (see Figure 21-38).
- Binding of extracellular death signals, such as tumor necrosis factor and Fas ligand, to their receptors oligomerizes and activates an associated protein (FADD) that in turn triggers the caspase cascade, leading to cell murder.

Perspectives for the Future

Cell birth, cell asymmetry, and cell death, which lie at the heart of the development, growth, and healing of an organism, are also central to disease processes, most notably cancer. Cell birth is normally carefully restricted to specific locales and times, such as the basal layer of the skin or the root meristem. Liver regenerates when there is injury, but liver cancer is prevented by restricting unnecessary growth at other times.

Some cells persist for the life of the organism, but others such as blood and intestinal cells turn over rapidly. Many cells live for a while and are then programmed to die and be replaced by others arising from a stem-cell population. Much attention is now being given to the regulation of stem cells in an effort to understand how self-renewing populations of cells are created and maintained. This has clear implications for repair of tissue: for example, to restore damaged retinas, torn cartilage, degenerating brain tissue, or failing organs. One interesting possibility is that some populations of stem cells with the potential to generate or regenerate tissue are normally eliminated by cell death during later development. If so, finding ways to selec-

tively block the death of these cells could make regeneration more likely. Could the elimination of such cells during mammalian development be the difference between an amphibian capable of limb regeneration and a mammal that is not?

ES and iPS cells will continue to provide a great deal of information about the regulatory molecules—transcription factors, chromatin- and DNA-modifying enzymes, and noncoding RNAs—and circuits that establish and maintain the pluripotent state, and that allow these cells to differentiate down specific developmental lineages. But the main interest in these cells—at least in the public's mind—is as a source of tissues to replace defective ones in many diseases. Several neurodegenerative diseases such as Alzheimer's and Parkinson's potentially could be cured *if* ES or iPS cells could be coaxed into differentiating in culture into appropriate neurons and *if* a method could be found to deliver these nerve cells to the appropriate regions of the brain. Similarly, ES and iPS cells can form normal-looking red blood cells and other types of blood cells in culture—but are these cells truly normal and completely functional, and can a bioengineering protocol be developed to make these cells in sufficient purity and numbers for transplantation into humans? Undoubtedly these problems, which are at the interface of tissue engineering and cellular and developmental biology, will eventually be solved—the question is, how soon?

Programmed cell death is the basis for the meticulous elimination of potentially harmful cells, such as autoreactive immune cells, which attack the body's own cells, or neurons that have failed to properly connect. Cell-death programs have also evolved as a defense against infection, and virus-infected cells are selectively murdered in response to death signals. Viruses, in turn, devote much of their effort to evading host defenses. Failures of programmed cell death can lead to uncontrolled cancerous growth. The proteins that prevent the death of cancer cells therefore become possible targets for drugs. As we learn in Chapter 24, many tumors contain a mixture of cells, some capable of seeding new tumors or continued uncontrolled growth and some capable only of growing in place or for a limited time. In this sense, the tumor has its own stem cells. These are now being identified and studied and are becoming vulnerable to medical intervention. One option is to manipulate the cell-death pathway by sending signals that will make cancer cells destroy themselves.

Key Terms

apoptosis 1007	germ line 987
apoptosome 1013	induced pluripotent
asymmetric cell division 977	stem (iPS) cell 978
Bcl-2 family 1011	meristem 995
BH3-only protein 1009	multipotent 978
caspases 1009	planar cell polarity
cell lineage 978	(PCP) 1003
embryonic stem (ES)	pluripotent 978
cell 978	polarity 997

precursor (progenitor) cell 986	stem-cell niche 987
programmed cell death 979	symmetric cell division 977
somatic cell 978	totipotent 977
stem cell 977	trophic factor 1006

Review the Concepts

1. What two properties define a stem cell? Distinguish between a totipotent stem cell, a pluripotent stem cell, and a precursor (progenitor) cell.
2. Where are stem cells located in plants? Where are stem cells located in adult animals? How does the concept of stem cell differ between animal and plant systems?
3. In 1997, Dolly the sheep was cloned by a technique called somatic-cell nuclear transfer (or nuclear-transfer cloning). A nucleus from an adult mammary cell was transferred into an egg from which the nucleus had been removed. The egg was allowed to divide several times in culture, then the embryo was transferred to a surrogate mother who gave birth to Dolly. Dolly died in 2003 after mating and giving birth herself to viable offspring. What does the creation of Dolly tell us about the potential of nuclear material derived from a fully differentiated adult cell? Does the creation of Dolly tell us anything about the potential of an intact, fully differentiated adult cell?
4. Identify whether the following contain totipotent, pluripotent, or multipotent cells: (a) inner cell mass, (b) morula, (c) eight-cell embryo, (d) trophectoderm.
5. True or false: Differentiated somatic cells have the capacity to become reprogrammed to become other cell types. Provide one line of evidence discussed in the chapter that corroborates your response.
6. Explain how intestinal stem cells were first identified and then experimentally established to be multipotent stem cells.
7. Explain how hematopoietic stem cells were shown experimentally to be both pluripotent and capable of self-renewal.
8. The roundworm *C. elegans* has proved to be a valuable model organism for studies of cell birth, cell asymmetry, and cell death. What properties of *C. elegans* render it so well suited for these studies? Why is so much information from *C. elegans* experiments of use to investigators interested in mammalian development?
9. Asymmetric cell division often relies on cytoskeletal elements to generate or maintain the asymmetric distribution of cellular factors. In *S. cerevisiae*, what factor is localized to the bud by myosin motors? In *Drosophila* neuroblasts, what factors are localized apically by microtubules?
10. Discuss the role of *par* genes in generating A-P polarity in the *C. elegans* embryo.
11. How do studies of brain development in knockout mice support the statement that apoptosis is a default pathway in neuronal cells?

12. Compare and contrast cell death by apoptosis and necrosis.
 13. Identify and list the functions of the three general classes of proteins that control cell death.
 14. Based on your understanding of the events surrounding cell death, predict the effect(s) of the following on the ability of a cell to undergo apoptosis:
 - a. Functional CED-9; nonfunctional CED-3
 - b. Active Bax and cytochrome c; nonfunctional caspase-9
 - c. Inactive PI-3 kinase; active Bad
 15. TNF and Fas ligand bind cell-surface receptors to trigger cell death. Although the death signal is generated external to the cell, why do we consider the death induced by these molecules to be apoptotic rather than necrotic?
 16. Predict the effects of the following mutations on the ability of a cell to undergo apoptosis:
 - a. Mutation in Bad such that it cannot be phosphorylated by protein kinase B (PKB)
 - b. Overexpression of Bcl-2
 - c. Mutation in Bax such that it cannot form homodimers
- One common characteristic of cancer cells is a loss of function in the apoptotic pathway. Which of the mutations listed above might you expect to find in some cancer cells?
17. How do IAPs (inhibitor of apoptosis proteins) interact with caspases to prevent apoptosis? How do mitochondrial proteins interact with IAPs to prevent inhibition of apoptosis?

Two principal types of cells in the central nervous system: neurons (red) and glial cells (green). In this image of the developing mouse optic nerve, axons are stained with an antibody against a principal component of myelin, myelin basic protein, that surrounds the long axons. Oligodendrocytes are a type of glial cell that produce the myelin coat, and are stained with an antibody specific to the β -catenin inhibitor adenomatous polyposis coli. [From B. Emery, 2010, *Science* **330**:779.]

The nervous system regulates all aspects of bodily function and is staggering in its complexity. The 1.3-kg adult human brain—the control center that stores, computes, integrates, and transmits information—contains about 10^{11} nerve cells, called neurons. These neurons are interconnected by some 10^{14} synapses, the junction points where two or more neurons communicate. Millions of specialized neurons sense features of both the external and internal environments of organisms and transmit this information to the brain for processing and storage. Millions of other neurons regulate the contraction of muscles and the secretion of hormones. The nervous system also contains glial cells, which occupy the spaces between neurons and modulate their functions.

NERVE CELLS

Despite the multiple types and shapes of neurons that are found in metazoan organisms, all nerve cells share many common properties. The structure and function of nerve cells is understood in great detail—perhaps in more detail than for any other cell type. The function of a neuron is to communicate information, which it does by two methods. *Electrical signals* process and conduct information within neurons, which are usually highly elongated cells (Figure 22-1). The electrical pulses that travel along neurons are called action potentials, and information is encoded as the frequency at which action potentials are fired. Owing to the speed of electrical transmission, neurons are champion signal transducers, much faster than cells that secrete hormones. In contrast to the electrical signals that conduct information *within* a

FIGURE 22-1 Typical morphology of two types of mammalian neurons. Action potentials arise in the axon hillock and are conducted toward the axon terminus. (a) A multipolar interneuron has profusely branched dendrites, which receive signals at synapses with several hundred other neurons. Small voltage changes imparted by inputs in the dendrites can sum to give rise to the more massive action potential, which starts in the hillock. A single long axon that branches laterally at its terminus *transmits* signals to other neurons. (b) A motor neuron innervating a muscle cell typically has a single long axon extending from the cell body to the effector cell. In mammalian motor neurons, an insulating sheath of myelin usually covers all parts of the axon except at the nodes of Ranvier and the axon termini. The myelin sheath is composed of cells called glia.

neuron, *chemical signals* transmit information *between* cells, utilizing processes similar to those employed by other types of signaling cells (Chapters 15 and 16).

Taken together, the electrical and chemical signaling of the nervous system allows it to detect external stimuli, integrate and process the information received, relay it to higher brain centers, and generate an appropriate response to the stimulus. For example, *sensory neurons* have specialized receptors that convert diverse types of stimuli from the environment (e.g., light, touch, sound, odors) into electrical signals. These electrical signals are then converted into chemical signals that are passed on to other cells called *interneurons*, which convert the information back into electrical signals. Ultimately the information is transmitted to muscle-stimulating *motor neurons* or to other neurons that stimulate other types of cells, such as glands.

In this chapter we will focus on neurobiology at the cellular and molecular level. We will start by looking at the general architecture of neurons and at how they carry signals. Next, we will focus on ion flow, channel proteins, and membrane properties: how electrical pulses move rapidly along neurons. Third, we will examine communication between neurons: electrical signals traveling along a cell must be translated into a chemical pulse between cells and then back into an electrical signal in the receiving cells. In the last section we will examine neurons in several sensory tissues, including those that mediate our senses of touch, taste, and olfaction. The speed, precision, and integrative power of neural signaling enable the accurate and timely sensory perception of a swiftly changing environment.

A great deal of information about nerve cells has been gleaned from analyses of humans, mice, nematodes, and flies with mutations that affect specific functions of the nervous system. In addition, molecular cloning and structural analysis of key neuronal proteins, such as voltage-gated ion channels and receptors, have helped elucidate the cellular machinery underlying complex brain functions such as instinct, learning, memory, and emotion.

22.1 Neurons and Glia: Building Blocks of the Nervous System

In this section we take an initial look at the structure of neurons and how they propagate electrical and chemical signals. **Neurons** are distinguished by their elongated, asymmetric shape, by their highly localized proteins and organelles, and most of all by a set of proteins that controls the flow of ions across the plasma membrane. Because one neuron can respond to the inputs from multiple neurons, generate electrical signals, and transmit the signals to multiple neurons, a nervous system has considerable powers of signal analysis. For example, a neuron might pass on a signal only if it receives five simultaneous activating signals from input neurons. The receiving neuron measures both the total *amount* of incoming signal and whether the five signals are roughly *synchronous*. Input from one neuron to another can be either *excitatory*—combining with other signals to trigger electrical transduction in the receiving cell—or *inhibitory*, discouraging such transmission. Thus the properties and connections of individual neurons set the stage for integration and refinement of information, and the output of a nervous system is the result of its circuit properties, that is, the wiring or interconnections between neurons, and the strength of these interconnections. We will begin by looking at how signals are received and sent, and in subsequent parts of the chapter we will look at the molecular details of the machinery involved.

Information Flows Through Neurons from Dendrites to Axons

Neurons arise from roughly spherical *neuroblast* precursors. Newly born neurons can migrate long distances before growing into dramatically elongated cells. Fully differentiated neurons take many forms, but generally share certain key features (see Figure 22-1). The nucleus is found in a rounded part of

the cell called the *cell body*. Branching cell processes called **dendrites** (from the Greek for “treelike”) are found at one end, and are the main structures where signals are received from other neurons via synapses. Incoming signals are also received at synapses that form on neuronal cell bodies. Neurons often have extremely long dendrites with complex branches, particularly in the central nervous system (i.e., the brain and spinal cord). This allows them to form synapses with, and receive signals from, a large number of other neurons—up to tens of thousands. Thus the converging dendritic branches allow signals from many cells to be received and integrated by a single neuron.

When a neuron is first differentiating, the end of the cell opposite the dendrites undergoes dramatic outgrowth to form a long extended arm called the **axon**, which is essentially a transmission wire. The growth of axons must be controlled so that proper connections are formed, a complex process called axon guidance that involves dynamic changes to the cytoskeleton and is discussed in Section 18.8. The diameters of axons vary from just a micrometer in certain neurons of the human brain to a millimeter in the giant fiber of the squid. Axons can be meters in length (in giraffe necks, for example), and are often partly covered with electrical insulation called the **myelin sheath** (see Figure 22-1b), which is made up of cells called *glia*. The insulation speeds electrical transmission and prevents short circuits. The short, branched ends of the axon at the opposite end of the neuron from the dendrites are called the *axon termini*. This is where signals are passed along to the next neuron or to another type of cell such as a muscle or hormone-secreting cell. The asymmetry of the neuron, with dendrites at one end and axon termini at the other, is indicative of the unidirectional flow of information from dendrites to axons.

Information Moves Along Axons as Pulses of Ion Flow Called Action Potentials

Nerve cells are members of a class of *excitable cells*, which also includes muscle cells, cells in the pancreas, and some others. Like all metazoan cells, excitable cells have an inside-negative voltage or electric potential gradient across their plasma membranes, the **membrane potential** (see Chapter 11). In excitable cells this potential can suddenly become zero or even reversed, with the inside of the cell positive with respect to the outside of the plasma membrane. The membrane voltage in a typical neuron, called the *resting potential* because it is the state when no signal is in transit, is established by Na^+/K^+ ion pumps in the plasma membrane. These are the same ion pumps used by other cells to generate a resting potential. Na^+/K^+ ion pumps use energy, in the form of ATP, to move positively charged Na^+ ions out of the cell and K^+ ions inward. Subsequent movement of K^+ out of the cell through resting K^+ channels results in a net negative charge inside the cell compared with the outside. The typical resting potential of a neuron is about -60 mV.

Neurons have a language all their own. They use their unique electrical properties to send signals. The signals take the form of brief local voltage changes, from inside-negative to

EXPERIMENTAL FIGURE 22-2 Recording of an axonal membrane potential over time reveals the amplitude and frequency of action potentials. An action potential is a sudden, transient depolarization of the membrane, followed by repolarization to the resting potential of about -60 mV. The axonal membrane potential can be measured with a small electrode placed into it (see Figure 11-19). This recording shows the neuron generating one action potential about every 4 milliseconds.

inside-positive, an event designated **depolarization**. A powerful surge of depolarizing voltage change, moving from one end of the neuron to the other, is called an **action potential**. “Depolarization” is somewhat of a misnomer, since the neuron suddenly goes from inside-negative to neutral to inside-positive, which could be more accurately described as depolarization followed by the opposite polarization (Figure 22-2). At the peak of an action potential, the membrane potential can be as much as $+50$ mV (inside-positive), a net change of about 110 mV. As we shall see in greater detail in Section 22.2, an action potential moves along the axon to the axon terminus at speeds of up to 100 meters per second. In humans, for instance, axons may be more than a meter long, yet it takes only a few milliseconds for an action potential to move along their length. Neurons can fire repeatedly after a brief recovery period, for example, every 4 milliseconds (ms), as in Figure 22-2. After the action potential passes a sector of a neuron, channel proteins and pumps restore the inside-negative resting potential (*repolarization*). The restoration process chases the action potential down the axon to the terminus, leaving the neuron ready to signal again.

Importantly, action potentials are “all or none.” Once the threshold to start one is reached, a full firing occurs. The signal information is therefore carried primarily not by the intensity of the action potentials, but by the timing and frequency of them.

Some excitable cells are not neurons. Muscle contraction is triggered by motor neurons that synapse directly on excitable muscle cells (see Figure 22-1b). Insulin secretion from the Beta cells of the pancreas is triggered by neurons. In both cases the activating event involves an opening of plasma membrane channels that causes changes in the transmembrane flow of ions and in the electrical properties of the regulated cells.

Information Flows Between Neurons via Synapses

What starts an action potential? Axon termini from one neuron are closely apposed to dendrites of another, at junctions called chemical synapses or simply **synapses** (Figure 22-3).

FIGURE 22-3 A Chemical Synapse. (a) A narrow region—the synaptic cleft—separates the plasma membranes of the presynaptic and postsynaptic cells. Arrival of action potentials in a presynaptic cell causes exocytosis at a synapse of a small number of synaptic vesicles, releasing their content of neurotransmitters (red circles). Following their diffusion across the synaptic cleft, the neurotransmitters bind to specific receptors on the plasma membrane of the postsynaptic cell. These signals either depolarize the postsynaptic membrane (making the potential inside less negative), tending to induce an action potential in the cell, or hyperpolarize the postsynaptic membrane (making the potential inside more negative), inhibiting action potential induction. (b) Electron micrograph showing a dendrite synapsing with an axon terminus filled with synaptic vesicles. In the synaptic region, the plasma membrane of the presynaptic cell is specialized for vesicle exocytosis; synaptic vesicles containing a neurotransmitter are clustered in these regions. The opposing membrane of the postsynaptic cell (in this case, a neuron) contains receptors for the neurotransmitter. [Part (b) from C. Raine et al., eds., 1981, *Basic Neurochemistry*, 3d ed., Little, Brown, p. 32.]

The axon termini of the *presynaptic cell* contain many small vesicles, termed **synaptic vesicles**, each of which is filled with a single kind of small molecule known as a **neurotransmitter**. Arrival of an action potential at a terminus triggers exocytosis of a small number of synaptic vesicles, releasing their content of neurotransmitter molecules.

Neurotransmitters diffuse across the synapse in about 0.5 ms and bind to receptors on the dendrite of the adjacent neuron. Binding of neurotransmitter triggers opening or closing of specific ion channels in the plasma membrane of *postsynaptic cell* dendrites, leading to changes in the membrane potential in this localized area of the postsynaptic cell. Generally these changes depolarize the postsynaptic membrane (making the potential less inside negative). The local depolarization, if large enough, triggers an action potential in the axon. Transmission is unidirectional, from the axon termini of the presynaptic cell to dendrites of the postsynaptic cell.

In some synapses, the effect of the neurotransmitters is to hyperpolarize and therefore lower the likelihood of an action potential in the postsynaptic cell. A single axon in the central nervous system can synapse with many neurons and induce responses in all of them simultaneously. Conversely, sometimes multiple neurons must act on the postsynaptic cell roughly synchronously to have a strong enough impact to trigger an action potential. Neuronal integration of depolarizing and hyperpolarizing signals determines the likelihood of an action potential.

Thus neurons employ a combination of extremely fast electrical transmission *along* the axon with rapid chemical communication *between* cells. Now we will look at how a chain of neurons, a circuit, can achieve a useful function.

The Nervous System Uses Signaling Circuits Composed of Multiple Neurons

In complex multicellular animals, such as insects and mammals, neurons form signaling circuits that are constructed using three basic types of nerve cells: afferent neurons, interneurons, and efferent neurons. **Afferent neurons**, also known as sensory or receptor neurons, carry nerve impulses from receptors or sense organs *toward* the central nervous system (i.e., the brain and spinal cord). These neurons report an event that has happened, like the arrival of a flash of light or the movement of a muscle. A touch or a painful stimulus creates a sensation in the brain only after information about the stimulus travels there via afferent nerve pathways. **Efferent neurons**, also known as effector neurons, carry nerve impulses *away* from the central nervous system to generate a response. A **motor neuron**, for example, carries a signal to a muscle to stimulate its contraction (see Figure 22-1b); other effector neurons stimulate hormone secretion by endocrine cells. **Interneurons**, the largest group, relay signals from afferent to efferent neurons and to other interneurons as part of a neural pathway. An interneuron can bridge multiple neurons, allowing integration or divergence of signals and sometimes extending the reach of a signal.

In a simple type of circuit called a *reflex arc*, interneurons connect multiple sensory and motor neurons, allowing one sensory neuron to affect multiple motor neurons and one

FIGURE 22-4 The knee-jerk reflex. A tap of the hammer stretches the quadriceps muscle, thus triggering electrical activity in the stretch receptor sensory neuron. The action potential, traveling in the direction of the top blue arrow, sends signals to the brain so we are aware of what is happening, and also to two kinds of cells in the dorsal-root ganglion that is located in the spinal cord. One cell, a motor neuron that connects back to the quadriceps (red), stimulates muscle

contraction so that you kick the person who hammered your knee. The second connection activates, or “excites,” an inhibitory interneuron (black). The interneuron has a damping effect, blocking activity by a flexor motor neuron (green) that would, in other circumstances, activate the hamstring muscle that opposes the quadriceps. In this way, relaxation of the hamstring is coupled to contraction of the quadriceps. This is a reflex because movement requires no conscious decision.

motor neuron to be affected by multiple sensory neurons; in this way interneurons integrate and enhance reflexes. For example, the knee-jerk reflex in humans, illustrated in Figure 22-4, involves a complex reflex arc in which one muscle is stimulated to contract while another is inhibited from contracting. The reflex also sends information to the brain to announce what happened. Such circuits allow an organism to respond to a sensory input by the coordinated action of sets of muscles that together achieve a single purpose.

These simple signaling circuits, however, do not directly explain higher-order brain functions such as reasoning, computation, and memory development. Typical neurons in the brain receive signals from up to a thousand other neurons and, in turn, can direct chemical signals to many other neurons. The output of the nervous system depends on its circuit properties—the amount of wiring, or interconnections, between neurons and the strength of these interconnections. Complex aspects of the nervous system, such as vision and consciousness, cannot be understood at the single-cell level, but only at the level of networks of nerve cells that can be studied by techniques of systems analysis. The nervous system is constantly changing; alterations in the number and nature of the interconnections between individual neurons occur, for example, in the formation of new memories.

Glial Cells Form Myelin Sheaths and Support Neurons

For all the impressiveness of neurons, they are a minority population of cells in the human brain. **Glial cells** (also known as *neuroglia* or simply *glia*), which play many roles in

the brain but do not themselves conduct electrical impulses, outnumber neurons by about 10 to 1. Of the three principal types of glia, two produce myelin sheaths—the insulation that surrounds neuronal axons (see Figure 22-1b): *oligodendrocytes* make sheaths for the central nervous system (CNS), and *Schwann cells* make them for the peripheral nervous system (PNS). (Both types of glia are discussed in more detail in Section 22.2.) *Astrocytes*, a third type of glia, provide growth factors and other signals to neurons, receive signals from neurons, and induce synapse formation between neurons.

Astrocytes, named for their starlike shape (Figure 22-5), constitute more than a third of the brain’s mass and half of the brain’s cells. Astrocytes surround many synapses and dendrites; the Ca^{2+} , K^{+} , Na^{+} , and Cl^{-} channels found in astrocyte plasma membranes influence the concentration of free ions in the extracellular space, thus affecting the membrane potentials of neurons and of the astrocytes themselves. Astrocytes produce abundant extracellular matrix proteins, some of which are used as guidance cues by migrating neurons, and a host of growth factors that carry a variety of types of information to neurons. Astrocytes are joined to each other by **gap junctions**, so changes in ionic composition in a given astrocyte are communicated to adjacent astrocytes, over distances of hundreds of microns.

Some astrocytes are also critical regulators of the formation of the blood-brain barrier, the purpose of which is to control what types of molecules can travel out of the bloodstream into the brain and vice versa (see Figure 22-5). Blood vessels in the brain supply oxygen and remove CO_2 , and deliver glucose and amino acids, with capillaries found within a few micrometers of every cell. These capillaries form the blood-brain barrier, which allows passage of oxygen and CO_2 across the

FIGURE 22-5 Astrocytes interact with endothelial cells at the blood-brain barrier. Capillaries in the brain are formed by endothelial cells that are interconnected by tight junctions that are impermeable to most molecules. Transport between cells is blocked, so only small molecules that can diffuse across plasma membranes or substances specifically transported through cells can cross the barrier. Certain astrocytes surround the blood vessels, in contact with the endothelial cells, and send secreted protein signals to induce the endothelial cells to produce a selective barrier. The endothelial cells (burgundy) are ensheathed by a layer of basal lamina (orange) and contacted on the outside by astrocyte processes (tan). [From N. J. Abbott, L. Rönnebeck, and E. Hansson, 2006, *Nature Rev. Neurosci.* 7:41–53.]

endothelial cell wall but prevents, for example, blood-borne circulating neurotransmitters and some drugs from entering the brain. The barrier consists of a set of tight junctions (Chapter 20) that interconnect the endothelial cells that form the walls of capillaries. Surrounding astrocytes promote specialization of these endothelial cells, making them less permeable than those in capillaries found in the rest of the body.

KEY CONCEPTS of Section 22.1

Neurons and Glia: Building Blocks of the Nervous System

- Neurons are highly asymmetric cells composed of multiple dendrites at one end, a cell body containing the nucleus, a long axon, and axon termini.
- Neurons carry information from one end to the other using pulses of ion flow across the plasma membrane. Branched

cell processes, dendrites, at one end of the cell receive chemical signals from other neurons, triggering ion flow. The electrical signal moves rapidly to axon termini at the other end of the cell (see Figure 22-1).

- A resting neuron carrying no signal has ATP-powered pumps that move ions across the plasma membrane. The outward movement of K^+ ions creates a net negative charge inside the cell. This voltage is called the resting potential and usually is about -60 mV (see Figure 22-2).
- If a stimulus causes certain ion channels to open so that certain ions can flow more freely, a strong pulse of voltage change may pass down the neuron from dendrites to axon termini. The cell goes from being -60 mV inside to $+50$ mV inside, relative to the extracellular fluid. This pulse is called an action potential (see Figure 22-2).
- The action potential travels down the length of the axon from the cell body to the axon termini at speeds of up to 100 meters per second.
- Neurons connect across small spaces called synapses. Since an action potential cannot jump the gap, at the axon termini of the presynaptic cell the signal is converted from electrical to chemical to stimulate the postsynaptic cell.
- Upon stimulation by an action potential, axon termini release, by exocytosis, small packets of chemicals called neurotransmitters. Neurotransmitters diffuse across the synapse and bind to receptors on the dendrites on the other side of the synapse. These receptors can induce or inhibit a new axon potential in the postsynaptic cell (see Figure 22-3).
- Neurons form circuits that usually consist of sensory neurons, interneurons, and motor neurons, as in the knee-jerk response (see Figure 22-4).
- Glial cells are ten times as abundant as neurons and serve many purposes. Oligodendrocytes and Schwann cells build the myelin insulation that coats many neurons.
- Astrocytes, another type of glial cell, wrap their processes around synapses and blood vessels and promote formation of the blood-brain barrier (see Figure 22-5). Astrocytes also secrete proteins that stimulate synapse formation.

22.2 Voltage-Gated Ion Channels and the Propagation of Action Potentials

In Chapter 11 we learned that an electric potential of approximately 70 mV (cytosolic face negative) exists across the plasma membrane of all cells, including resting nerve cells. This resting membrane potential is generated by outward movement of K^+ ions through open nongated K^+ channels in the plasma membrane, and is driven by the K^+ concentration gradient (cytosol $>$ extracellular medium). The high cytosolic K^+ and low cytosolic Na^+ concentrations, relative to their concentrations in the extracellular medium, are generated by the plasma membrane Na^+/K^+ pump, which uses the energy released by hydrolysis of phosphoanhydride bonds in ATP to pump Na^+ outward and K^+ inward. The entry of Na^+ ions into the cytosol from the medium is thermodynamically favored, driven both by the Na^+ concentration gradient (extracellular medium $>$ cytosol) and the inside-negative membrane potential (see Figure 11-25). However, most Na^+ channels in the plasma membrane are closed in resting cells, so little inward movement of Na^+ ions can occur (Figure 22-6a).

During an action potential, some of these Na^+ channels open, allowing inward movement of Na^+ ions, which depolarizes the membrane. Action potentials are propagated

down the axon because a change in voltage in one part of the axon triggers the opening of channels in the next section of the axon. Such *voltage-gated channels* therefore lie at the heart of neural transmission. In this section, we first introduce some of the key properties of action potentials, which move rapidly along the axon from the cell body to the termini. We then describe how the voltage-gated channels responsible for propagating action potentials in neurons operate. In the last part of the section, we will see how the myelin sheath, produced by glial cells, increases the speed and efficiency of electrical transmission in nerve cells.

The Magnitude of the Action Potential Is Close to E_{Na} and Is Caused by Na^+ Influx Through Open Na^+ Channels

Figure 22-6b illustrates how the membrane potential will change if enough Na^+ channels in the plasma membrane become opened. The resulting influx of positively charged Na^+ ions into the cytosol will more than compensate for the efflux of K^+ ions through open resting K^+ channels. The result will be a *net* inward movement of cations, generating an excess of positive charges on the cytosolic face of the plasma membrane and a corresponding excess of negative charges on the extracellular face (owing to the Cl^- ions “left behind” in the extracellular medium after influx of Na^+ ions). In other words, the plasma membrane becomes depolarized to such an extent that the inside face becomes positive with respect to the external face.

Recall from Chapter 11 that the equilibrium potential of an ion is the membrane potential at which there is no net flow of that ion from one side of the membrane to the other due to the balancing of two opposing forces, the ion concentration gradient and the membrane potential. At the peak of depolarization in an action potential, the magnitude of the membrane potential is very close to the Na^+ equilibrium potential E_{Na} given by the Nernst equation (Equation 11-2), as would be expected if opening of voltage-gated Na^+ channels is responsible for generating action potentials. For example, the measured peak value of the action potential for the squid giant axon is +35 mV, which is close to the calculated value of E_{Na} (+55 mV) based on Na^+ concentrations of 440 mM outside and 50 mM inside. The relationship between the magnitude of the action potential and the concentration of Na^+ ions inside and outside the cell has been confirmed experimentally. For instance, if the concentration of Na^+ ions in the solution bathing the squid axon is reduced to one-third of normal, the magnitude of the depolarization is reduced by 40 mV, nearly as predicted.

FIGURE 22-6 Depolarization of the plasma membrane due to opening of gated Na^+ channels. (a) In resting neurons, a type of nongated K^+ channel is open part of the time, but the more numerous gated Na^+ channels are closed. The movement of K^+ ions outward establishes the inside-negative membrane potential characteristic of most cells. (b) Opening of gated Na^+ channels permits an influx of sufficient Na^+ ions to cause a reversal of the membrane potential. In the depolarized state, voltage-gated K^+ channels open and subsequently repolarize the membrane. Note that the flows of ions are too small to have much effect on the overall concentration of either Na^+ or K^+ in the cytosol or exterior fluid.

Sequential Opening and Closing of Voltage-Gated Na^+ and K^+ Channels Generate Action Potentials

The cycle of changes in membrane potential and return to the resting value that constitutes an action potential lasts 1–2 milliseconds and can occur hundreds of times a second in a typical neuron (see Figure 22-2). These cyclical changes

in the membrane potential result from the opening and closing first of a number of *voltage-gated Na⁺ channels* (that is, channels opened by a *change* in membrane potential) in a segment of the axonal plasma membrane, and then opening and closing of *voltage-gated K⁺ channels*. The role of these channels in the generation of action potentials was elucidated in classic studies done on the giant axon of the squid, in which multiple microelectrodes can be inserted without causing damage to the integrity of the plasma membrane. However, the same basic mechanism is used by all neurons.

Voltage-Gated Na⁺ Channels As just discussed, voltage-gated Na⁺ channels are closed in resting neurons. A small depolarization of the membrane (as occurs when neurotransmitter stimulates a postsynaptic cell) increases the likelihood that any one channel will open; the greater the depolarization the greater the probability that a channel will open. Depolarization causes a conformational change in these channel proteins that opens a gate on the cytosolic surface of the pore, permitting Na⁺ ions to pass through the pore into the cell. Thus the greater the initial membrane depolarization, the more voltage-gated Na⁺ channels that open and the more Na⁺ ions that enter.

As Na⁺ ions flow inward through opened channels, the excess positive charges on the cytosolic face and negative charges on the exoplasmic face diffuse a short distance away from the initial site of depolarization. This *passive spread* of positive charges on the cytosolic face and negative charges on the external face depolarizes (makes the inside less negative) adjacent segments of the plasma membrane, causing opening of additional voltage-gated Na⁺ channels in these segments and an increase in Na⁺ influx. As more Na⁺ ions enter the cell, the inside of the cell membrane becomes more depolarized, causing the opening of yet more voltage-gated Na⁺ channels and even more membrane depolarization, setting into motion an explosive entry of Na⁺ ions. For a fraction of a millisecond, the permeability of this small segment of the membrane to Na⁺ becomes vastly greater than that for K⁺, and the membrane potential approaches E_{Na} , the equilibrium potential for a membrane permeable only to Na⁺ ions. As the membrane potential approaches E_{Na} , however, further net inward movement of Na⁺ ions ceases, since the concentration gradient of Na⁺ ions (outside > inside) is now offset by the inside-positive membrane potential. The action potential is, at its peak, close to the value of E_{Na} .

Figure 22-7 schematically depicts the critical structural features of voltage-gated Na⁺ channels and the conformational

FIGURE 22-7 Operational model of the voltage-gated Na⁺ channel.

As in the K⁺ channel depicted in Figure 11-20, four transmembrane domains in the protein contribute to the central pore through which ions move. The critical components that control movement of Na⁺ ions are shown here in the cutaway views depicting three of the four transmembrane domains. In the closed, resting state, the voltage-sensing α helices, which have positively charged side chains every third residue, are attracted to the negative charges on the cytosolic side of the resting membrane. This keeps the gate segment near the cytosolic face in a "closed" position that blocks the channel, preventing entry of Na⁺ ions (step 1). In response to a small depolarization, the voltage-sensing helices move

through the phospholipid bilayer toward the outer membrane surface, causing an immediate conformational change in the gate at the cytosolic face of the protein that opens the channel (step 2). Within a fraction of a millisecond the channel-inactivating segment moves into the open channel, preventing passage of further ions (step 3). Once the membrane is repolarized, the voltage-sensing helices return to the resting position, the channel-inactivating segment is displaced from the channel opening, and the gate closes; the protein reverts to the closed, resting state and can be opened again by depolarization (step 1). [See W. A. Catterall, 2001, *Nature* 409:988; and S. B. Long et al., 2007, *Nature* 450:376.]

EXPERIMENTAL FIGURE 22-8 Probability of channel opening and current flux through individual voltage-gated K^+ channels increases with the extent of membrane depolarization. These patch-clamp tracings were obtained from patches of neuronal plasma membrane clamped at three different potentials, +50, +20, and -10 mV. The upward deviations in the current indicate the opening of K^+ channels and movement of K^+ ions outward (cytosolic to exoplasmic face) across

the membrane. Increasing the membrane depolarization (i.e., the clamping voltage) from -10 mV to +50 mV increases the probability a channel will open, the time it stays open, and the amount of electric current (numbers of ions) that pass through it. pA = picoamperes. [From B. Pallota et al., 1981, *Nature* **293**:471, as modified by B. Hille, 1992, *Ion Channels of Excitable Membranes*, 2d ed., Sinauer, p. 122.]

changes that cause their opening and closing. In the resting state, a segment of the protein on the cytosolic face—the *gate*—obstructs the central pore, preventing passage of ions. The channel contains four positively charged *voltage-sensing α helices*; in the resting state these helices are attracted to the inside-negative surface of the plasma membrane. A small depolarization of the membrane triggers movement of these voltage-sensing helices toward the negative charges that are building up on the exoplasmic surface, causing a conformational change in the gate that opens the channel and allows Na^+ ion flow. After about 1 ms, further Na^+ influx is prevented by movement of the cytosol-facing *channel-inactivating segment* into the open channel, blocking any further movement of Na^+ ions. As long as the membrane remains depolarized, the channel-inactivating segment remains in the channel opening; during this *refractory period*, the channel is inactivated and cannot be reopened. A few milliseconds after the inside-negative resting potential is reestablished, the channel-inactivating segment swings away from the pore and the voltage-sensing α helices return to their resting position near the cytosolic surface of the membrane. Thus the channel returns to the closed resting state, once again able to be opened by depolarization. Note the important distinction between “closed” channels and those that are “inactive” as depicted in Figure 22-7.

Voltage-Gated K^+ Channels The repolarization of the membrane that occurs during the refractory period is due largely to opening of voltage-gated K^+ channels. The subsequent increased efflux of K^+ from the cytosol removes the excess positive charges from the cytosolic face of the plasma membrane (i.e., makes it more negative), thereby restoring the inside-negative resting potential. For a brief instant, the membrane actually becomes hyperpolarized; at the peak of this **hyperpolarization**, the potential approaches E_K , which is more negative than the resting potential (see Figure 22-2).

Opening of the voltage-gated K^+ channels is induced by the large depolarization of the action potential. Unlike voltage-gated Na^+ channels, most types of voltage-gated

K^+ channels remain open as long as the membrane is depolarized, and close only when the membrane potential has returned to an inside-negative value. Because the voltage-gated K^+ channels open slightly after the initial depolarization, at the height of the action potential, they sometimes are called *delayed K^+ channels*. Eventually all the voltage-gated K^+ and Na^+ channels return to their closed resting states. The only open channels in this baseline condition are the nongated K^+ channels that generate the resting membrane potential, which soon returns to its usual value of approximately -70 mV (see Figure 22-6a).

While the flow of Na^+ and K^+ ions alters membrane potential dramatically as it is depolarized, hyperpolarized, and repolarized during an action potential cycle, it is important to note that the exchange of these ions across the membrane is small compared to the overall numbers of Na^+ and K^+ ions in the cytosol and extracellular space. Thus, the conduction of action potentials in neurons does not *directly* require the Na^+/K^+ pumps that maintain their ion concentration gradients, as we will see shortly.

Voltage-gated Na^+ channels are difficult to study using patch-clamp techniques, but the patch-clamp tracings in Figure 22-8 reveal the essential properties of voltage-gated K^+ channels (see Figure 11-22 for a description of patch clamping). In this experiment, small segments of a neuronal plasma membrane were held clamped at different voltages, and the flux of electric charges through the patch due to flow of K^+ ions through open K^+ channels was measured. At the modest depolarizing voltage of -10 mV, the channels in the membrane patch open infrequently and remain open for only a few milliseconds, as judged, respectively, by the number and width of the upward blips on the tracings. Further, the ion flux through them is rather small, as measured by the electric current passing through each open channel (the height of the blips). Depolarizing the membrane further to +20 mV causes these channels to open about twice as frequently; also, more K^+ ions move through each open channel (the height of the blips is greater) because the force driving cytosolic K^+ ions outward is greater at a membrane

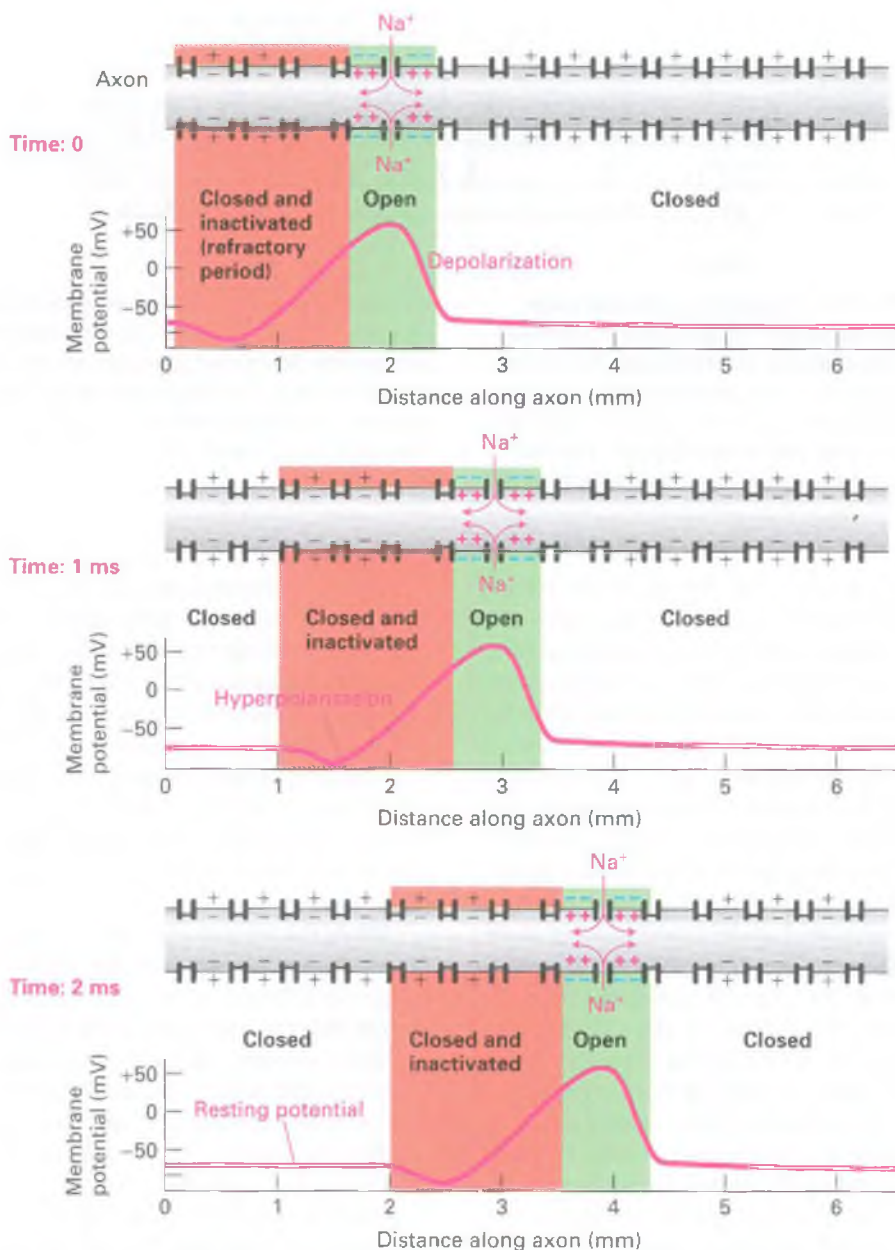

FIGURE 22-9 Unidirectional conduction of an action potential due to transient inactivation of voltage-gated Na⁺ channels. At time 0, an action potential (pink line) is at the 2-mm position on the axon; the Na⁺ channels at this position are open (green shading) and Na⁺ ions are flowing inward. The excess Na⁺ ions diffuse in both directions along the inside of the membrane, passively spreading the depolarization in both directions (curved pink arrows). But because the Na⁺ channels at the 1-mm position are still inactivated (red shading),

they cannot yet be reopened by the small depolarization caused by passive spread; the Na⁺ channels at the "downstream" 3-mm position, in contrast, begin to open. Each region of the membrane is refractory (inactive) for a few milliseconds after an action potential has passed. Thus, the depolarization at the 2-mm site at time 0 triggers action potentials downstream only; at 1 ms an action potential is passing the 3-mm position, and at 2 ms an action potential is passing the 4-mm position.

potential of +20 mV than at -10 mV. Depolarizing the membrane further to +50 mV, the value at the peak of an action potential, causes opening of more K⁺ channels and also increases the flux of K⁺ through them. Thus, by opening during the peak of the action potential, these K⁺ channels permit the outward movement of K⁺ ions and repolarization of the membrane potential while the voltage-gated Na⁺ channels are being closed and inactivated.

More than 100 voltage-gated K⁺ channel proteins have been identified in humans and other vertebrates. As we discuss later, all these channel proteins have a similar overall structure, but they exhibit different voltage dependencies, conductivities, channel kinetics, and other functional properties. Many open only at strongly depolarizing voltages, a property required for generation of the maximal depolarization characteristic of the action potential before repolarization of the membrane begins.

Action Potentials Are Propagated Unidirectionally Without Diminution

An action potential begins with changes that occur in a small patch of the axonal plasma membrane near the cell body. At the peak of the action potential, passive spread of the membrane depolarization is sufficient to depolarize a neighboring segment of membrane. This causes a few voltage-gated Na^+ channels in this region to open, thereby increasing the extent of depolarization in the region and causing an explosive opening of more Na^+ channels and generation of an action potential. This depolarization soon triggers opening of voltage-gated K^+ channels and restoration of the resting potential. The action potential thus spreads as a traveling wave away from its initial site without diminution.

As noted earlier, during the refractory period voltage-gated Na^+ channels are inactivated for several milliseconds. Such refractory channels cannot conduct ion movements and cannot open during this period even if the membrane is depolarized owing to passive spread. As illustrated in Figure 22-9, the inability of Na^+ channels to reopen during the refractory period ensures that action potentials are propagated only in one direction, from the initial axon segment where they originate to the axon termini. Because the Na^+ channels upstream of the location of the action potential are still inactivated they cannot be reopened by the small depolarization caused by passive spread. In contrast, the Na^+ channels “downstream” of the action potential begin to open.

The refractory period of the Na^+ channels also limits the number of action potentials that a neuron can conduct per second. This is important, since it is the frequency of action potentials that carries the information. Reopening of Na^+ channels upstream of an action potential (i.e., closer to the cell body) also is delayed by the membrane hyperpolarization that results from opening of voltage-gated K^+ channels.

Nerve Cells Can Conduct Many Action Potentials in the Absence of ATP

The depolarization of the membrane during an action potential results from movement of just a small number of Na^+ ions into a neuron and does not significantly affect the intracellular Na^+ concentration. A typical nerve cell has about 10 voltage-gated Na^+ channels per square micrometer (μm^2) of plasma membrane. Since each channel passes about 5000–10,000 ions during the millisecond it is open (see Figure 11-23), a maximum of 10^5 ions per μm^2 of plasma membrane will move inward during each action potential.

To assess the effect of this ion flux on the cytosolic Na^+ concentration of 10 mM (0.01 mol/L) typical of a resting axon, we focus on a segment of axon 1 micrometer (μm) long and 10 μm in diameter. The volume of this segment is $78 \mu\text{m}^3$, or 7.8×10^{-13} liters, and it contains 4.7×10^9 Na^+ ions: (10^{-2} mol/L) (7.8×10^{-13} L) (6×10^{23} Na^+ /mol). The surface area of this segment of the axon is $31 \mu\text{m}^2$, and during passage of one action potential, 10^5 Na^+ ions will enter per μm^2 of membrane. Thus this Na^+ influx increases the

number of Na^+ ions in this segment by only one part in about 1500: (4.7×10^9) / (3.1×10^6). Likewise, the repolarization of the membrane due to the efflux of K^+ ions through voltage-gated K^+ channels does not significantly change the intracellular K^+ concentration.

Because relatively few Na^+ and K^+ ions move across the plasma membrane during each action potential, the ATP-driven Na^+/K^+ pump that maintains the usual ion gradients plays no direct role in impulse conduction. Since the ion movements during each action potential involve only a minute fraction of the cell's K^+ and Na^+ ions, a nerve cell can fire hundreds or even thousands of times in the absence of ATP.

All Voltage-Gated Ion Channels Have Similar Structures Having explained how the action potential is dependent on regulated opening and closing of voltage-gated channels, we turn to a molecular dissection of these remarkable proteins. After describing the basic structure of these channels, we focus on three questions:

- How do these proteins sense changes in membrane potential?
- How is this change transduced into opening of the channel?
- What causes these channels to become inactivated shortly after opening?

The initial breakthrough in understanding voltage-gated ion channels came from analysis of fruit flies (*Drosophila melanogaster*) carrying the *shaker* mutation. These flies shake vigorously under ether anesthesia, reflecting a loss of motor control and a defect in certain motor neurons that have an abnormally prolonged action potential. Researchers suspected that the *shaker* mutation caused a defect in channel function. Cloning of the gene involved confirmed that the defective protein was a voltage-gated K^+ channel. The *shaker* mutation prevents the mutant channel from opening normally immediately upon depolarization. To establish that the wild-type *shaker* gene encoded a K^+ channel, cloned wild-type *shaker* cDNA was used as a template to produce *shaker* mRNA in a cell-free system. Expression of this mRNA in frog oocytes and patch-clamp measurements on the newly synthesized channel protein showed that its functional properties were identical with those of the voltage-gated K^+ channel in the neuronal membrane, demonstrating conclusively that the *shaker* gene encodes this K^+ -channel protein.

The Shaker K^+ channel and most other voltage-gated K^+ channels that have been identified are tetrameric proteins composed of four identical subunits arranged in the membrane around a central pore. Each subunit is constructed of six membrane-spanning α helices, designated S1–S6, and a P segment (Figure 22-10a). The S5 and S6 helices and the P segment are structurally and functionally homologous to those in the nongated resting K^+ channel discussed earlier (see Figure 11-20); the S5 and S6 helices form the lining of the K^+ selectivity filter through which the ion travels. The S1–S4 helices form a rigid complex that functions as a voltage sensor (with positively charged side chains in S4 acting as the primary sensor). The N-terminal “ball” extending into the cytosol from S1 is the channel-inactivating segment.

FIGURE 22-10 Schematic depictions of the secondary structures of voltage-gated K⁺ and Na⁺ channels. (a) Voltage-gated K⁺ channels are composed of four identical subunits, each containing 600–700 amino acids, and six membrane-spanning α helices, S1–S6. The N-terminus of each subunit, located in the cytosol and labeled N, forms a globular domain (orange ball) essential for inactivation of the open channel. The S5 and S6 helices (green) and the P segment (blue) are homologous to those in nongated resting K⁺ channels, but each subunit contains four additional transmembrane α helices. One of these, S4 (red), is the primary voltage-sensing α helix and is assisted

in this role by forming a stable complex with helices S1–3. (b) Voltage-gated Na⁺ channels are monomers containing 1800–2000 amino acids organized into four transmembrane domains (I–IV) that are similar to the subunits in voltage-gated K⁺ channels. The single hydrophobic channel-inactivating segment (orange ball) is located in the cytosol between domains III and IV. Voltage-gated Ca²⁺ channels have a similar overall structure. Most voltage-gated ion channels also contain regulatory (β) subunits, which are not depicted here. [Part (a) adapted from C. Miller, 1992, *Curr. Biol.* **2**:573, and H. Larsson et al., 1996, *Neuron* **16**:387; part (b) adapted from W. A. Catterall, 2001, *Nature* **409**:988.]

Voltage-gated Na⁺ channels and Ca²⁺ channels are monomeric proteins organized into four homologous domains, I–IV (Figure 22-10b). Each of these domains is similar to a subunit of a voltage-gated K⁺ channel. However, in contrast to voltage-gated K⁺ channels, which have four channel-inactivating segments, the monomeric voltage-gated channels have a single channel-inactivating segment. Except for this minor structural difference and their varying ion permeabilities, all voltage-gated ion channels are thought to function in a similar manner and to have evolved from a monomeric ancestral channel protein that contained six transmembrane α helices. Since no molecular structure is available for a voltage-gated Ca²⁺ channel, and there is a molecular structure available only for a closed voltage-gated Na⁺ channel, our discussion focuses on voltage-gated K⁺ channels.

Voltage-Sensing S4 α Helices Move in Response to Membrane Depolarization

Our understanding of channel-protein biochemistry is advancing rapidly owing to newly obtained crystal structures for bacterial and Shaker potassium channels and other channels.

Transmembrane proteins are notoriously difficult to produce and crystallize, posing unique challenges for the scientist. One method used to obtain crystals of these difficult membrane proteins was to surround them with bound fragments of monoclonal antibodies [F(ab)²s; Chapter 23]; in other cases they were crystallized in complexes with normal protein-binding partners. In both cases the presence of these water-soluble proteins in the complex somehow enhanced crystal formation.

The structures of the channels reveal remarkable arrangements of the voltage-sensing domains, and suggest how parts of the protein move in order to open the channel. As already noted, the K⁺-channel tetramer has a pore whose walls are formed by helices S5 and S6 (Figure 22-11a, b). Outside that core structure four arms, or “paddles,” each containing helices S1–S4, protrude into the surrounding membrane and also interact with the outer sides of the S5 and S6 helices; these are the voltage sensors, and they are in minimal contact with the pore. Sensitive electrical measurements suggested that the opening of a voltage-gated Na⁺ or K⁺ channel is accompanied by the movement of 12 to 14 protein-bound positive charges from the cytosolic to the

FIGURE 22-11 Molecular structure of a voltage-sensitive K⁺ channel. The two ribbon diagrams show models of the potassium channel in the (a) open and (b) closed states. Since the molecule is a tetramer of the same subunit, four copies of each helix are visible. The four green (S5) and blue (S6) α helices span the membrane, with the interior of the cell at the bottom and exterior at the top. Note how the helices are tightly packed at the bottom in (b), closing the channel so that the K⁺ ion cannot pass through. (Compare the distances between S5 helices as shown by the curly brackets below (a) and (b).) The S4-S5 linker (orange), located in the cytoplasm, connects the S4 helix (not shown) to the S5 helix. For clarity, helices S1 through S4 have been omitted from the model; they would normally be attached to the end of the S4-S5 linker and protrude from the molecule. (c) Three-

dimensional structure of the voltage-sensing "paddles" comprising helices S1-S4, with the four voltage-sensing arginine (R) residues in S4 (depicted in panel d). These paddles move from near the interior to the exterior of the membrane in response to depolarization. Since each one is attached to an S4-S5 linker, each linker and its attached S5 helix is moved, in turn moving S6 helices, which opens the pore. Note that the linker between S4 and S5 is pointed upward toward the exoplasmic (exterior) surface in the open channel (a), pulled upward by the outward movement of the S1-S4 paddles; in contrast the S4-S5 linker is pointing downward in the closed channel (b) when the S1-S4 paddles are nearer the cytosolic surface. (d) Three-dimensional structure of helix S4 and the S4-S5 linker. [From S. B. Long, X. Tao, E. B. Campbell, and R. MacKinnon, 2007, *Nature* **450**:376-382.]

exoplasmic surface of the membrane. The moving parts of the protein are the rigid complexes composed of helices S1-S4; S4 accounts for much of the positive charge and is the primary voltage sensor, with a positively charged lysine or arginine every third or fourth residue (Figure 21-11d). Arginines in S4 have been measured moving as much as 1.5 nm as the channel opens, which can be compared with the ~5-nm thickness of the membrane or the 1.2-nm diameter of the α helix itself.

In the resting state, the positive charges on the S1-S4 complexes (the "paddles") are attracted to the negative charges on the cytosolic face of the membrane. In the depolarized membrane, these same positive charges become attracted to the negative charges on the exoplasmic (outer) surface of the membrane, causing the S1-S4 paddles to move partly across the membrane—from the cytosolic to the exo-

plasmic surface. This movement is depicted schematically in Figure 22-7 and triggers a conformational change in the protein that opens the channel.

The most unusual aspect of the voltage-sensitive channel structures is the presence of charged groups, e.g., arginines, in contact with lipid. The location of the voltage sensor helps to explain earlier experiments in which a non-voltage-sensitive channel was converted into a voltage-sensing channel by adding to it voltage-sensing domains. Such a result would seem unlikely if the voltage sensors had to be deeply embedded in the core structure.

Studies with mutant Shaker K⁺ channels support the importance of the S4 helix in voltage sensing. When one or more arginine or lysine residues in the S4 helix of the Shaker K⁺ channel were replaced with neutral or acidic residues, fewer positive charges than normal moved across the membrane in

EXPERIMENTAL FIGURE 22-12 Experiments with a mutant K^+ channel lacking the N-terminal globular domains support the ball-and-chain inactivation model. The wild-type Shaker K^+ channel and a mutant form lacking the amino acids composing the N-terminal ball were expressed in *Xenopus* oocytes. The activity of the channels was monitored by the patch-clamp technique. When patches were depolarized from 0 to +30 mV, the wild-type channel opened for ~5 ms and then closed (red curve). The mutant channel opened normally, but could not close (green curve). When a chemically synthesized ball peptide was added to the cytosolic face of the patch, the mutant channel opened normally and then closed (blue curve). This demonstrated that the added peptide inactivated the channel after it opened and that the ball does not have to be tethered to the protein in order to function. [Adapted from W. N. Zagotta et al., 1990, *Science* 250:568.]

response to a membrane depolarization, indicating that arginine and lysine residues in the S4 helix do indeed move across the membrane. The structure of the open form of a mammalian voltage-gated K^+ channel has been contrasted with the closed structure of a different K^+ channel. The results suggest a model for the opening and closing of the channel in response to movements of the voltage sensors across the membrane (see Figure 22-11a, b). In the model, the voltage sensors, composed of helices S1–S4, move in response to voltage and exert a torque on a linker helix that connects S4 to S5:

- In the open-channel conformation, the position of the S4–S5 linker forces the S6 helix to form a kink near the cytosolic surface (blue in Figure 22-11a) and the pore inside, near the cytosolic surface, is open. The pore's 1.2-nm diameter is sufficient to accommodate hydrated K^+ ions.
- When the cell membrane is repolarized and the voltage sensor moves toward the cytosolic membrane surface, the S4–S5 linkers (orange in Figure 22-11b) are twisted down, toward the inside of the cell. The S6 helices are consequently straightened, squeezing the bottom of the channel closed. Thus the gate is composed of the cytosol-facing ends of the S5 and S6 helices, where the pore is narrowest.

Movement of the Channel-Inactivating Segment into the Open Pore Blocks Ion Flow

An important characteristic of most voltage-gated channels is inactivation; that is, soon after opening they close spontaneously, forming an inactive channel that will not reopen until the membrane is repolarized. In the resting state, the globular balls at the N-termini of the four subunits in a voltage-gated K^+ channel are free in the cytosol (Figure 22-10). Several milliseconds after the channel is opened by depolarization, one ball moves through an opening between two of the subunits and binds in a hydrophobic pocket in the pore's central cavity, blocking the flow of K^+ ions (Figure 22-7). After a few milliseconds, the ball is displaced from the pore, and the pro-

tein reverts to the closed, resting state. The ball-and-chain domains in K^+ channels are functionally equivalent to the channel-inactivating segment in Na^+ channels.

The experimental results shown in Figure 22-12 demonstrate that inactivation of K^+ channels depends on the ball domains, occurs after channel opening, and does not require the ball domains to be covalently linked to the channel protein. In other experiments, mutant K^+ channels lacking portions of the ~40-residue chain connecting the ball to the S1 helix were expressed in frog oocytes. Patch-clamp measurements of channel activity showed that the shorter the chain, the more rapid the inactivation, as if a ball attached to a shorter chain can move into the open channel more readily. Conversely, addition of random amino acids to lengthen the normal chain slows channel inactivation.

The single channel-inactivating segment in voltage-gated Na^+ channels contains a conserved hydrophobic motif composed of isoleucine, phenylalanine, methionine, and threonine (see Figure 22-10b). Like the longer ball-and-chain domain in K^+ channels, this segment folds into and blocks the Na^+ -conducting pore until the membrane is repolarized (see Figure 22-7).

Myelination Increases the Velocity of Impulse Conduction

As we have seen, action potentials can move down an unmyelinated axon without diminution at speeds up to 1 meter per second. But even such fast speeds are insufficient to permit the complex movements typical of animals. In adult humans, for instance, the cell bodies of motor neurons innervating leg muscles are located in the spinal cord, and the axons are about a meter in length. The coordinated muscle contractions required for walking, running, and similar movements would be impossible if it took 1 second for an action potential to move from the spinal cord down the axon of a motor neuron to a leg muscle. The solution is to wrap cells in insulation that increases the rate of movement of an action potential. The insulation is called a **myelin sheath** (see Figure 22-1b). The presence of a myelin sheath around an axon increases the velocity of impulse conduction to 10–100 meters per second. As a result, in a typical human motor neuron, an action potential can travel the length of a 1-meter-long axon and stimulate a muscle to contract within 0.01 seconds.

In nonmyelinated neurons, the conduction velocity of an action potential is roughly proportional to the diameter of the axon, because a thicker axon will have a greater number of ions that can diffuse. The human brain is packed with relatively small, myelinated neurons. If the neurons in the human brain were not myelinated, their axonal diameters would have to increase about 10,000-fold to achieve the same conduction velocities as myelinated neurons. Thus vertebrate brains, with their densely packed neurons, never could have evolved without myelin.

Action Potentials “Jump” from Node to Node in Myelinated Axons

The myelin sheath surrounding an axon is formed from many glial cells. Each region of myelin formed by an individual glial cell is separated from the next region by an unmyelinated area of axonal membrane about 1 μm in length called the *node of Ranvier* (or simply, *node*; see Figure 22-1b). The axonal membrane is in direct contact with the extracellular fluid only at the nodes, and the myelin covering prevents any ion movement into or out of the axon except at the nodes. Moreover, all the voltage-gated Na^+ and K^+ channels and all the Na^+/K^+ pumps, which maintain the ionic gradients in the axon, are located in the nodes.

As a consequence of this localization, the inward movement of Na^+ ions that generates the action potential can occur only at the myelin-free nodes (Figure 22-13). The excess cytosolic positive ions generated at a node during the membrane depolarization associated with Na^+ movement into the cytosol as part of an action potential spread passively through the axonal cytosol to the next node with very little loss or attenuation, since they cannot cross the myelinated axonal membrane. This causes a depolarization at one node to spread rapidly to the next node and induce an action potential there, effectively permitting the action potential to jump from node to node. The transmission is called *saltatory conduction*. This phenomenon explains why the conduction velocity of myelinated neurons is about the same as that of much-larger-diameter unmyelinated neurons. For instance, a 12- μm -diameter myelinated vertebrate axon and a 600- μm -diameter unmyelinated squid axon both conduct impulses at 12 m/s.

Two Types of Glia Produce Myelin Sheaths

Figure 22-14 shows three main types of glial cells present in the nervous system, two of which produce myelin sheaths: *oligodendrocytes* make sheaths for the central nervous system (CNS), and *Schwann cells* make them for the peripheral nervous system (PNS). Astrocytes, also shown in the figure, facilitate synapse formation and communication between neurons, and were discussed in Section 22.1. A fourth type of glia, *microglia* (not shown), constitutes a part of the CNS immune system. Microglia are not related by lineage to neurons or to other glia, and will not be discussed further.

FIGURE 22-13 Conduction of action potentials in myelinated axons. Because the myelin layer renders the axon impermeable to ion movement across its membrane and because voltage-gated Na^+ channels are found only on axonal membrane at the nodes of Ranvier, the influx of Na^+ ions associated with an action potential can occur only at nodes. When an action potential is generated at one node (step 1), the excess positive ions in the cytosol, which cannot move outward across the sheath, diffuse rapidly down the axon, causing sufficient depolarization at the next node (step 2) to induce an action potential at that node (step 3). By this mechanism the action potential jumps from node to node along the axon.

Oligodendrocytes Oligodendrocytes form the spiral myelin sheath around axons of the central nervous system (Figure 22-14a). Each oligodendrocyte provides myelin sheaths to segments of multiple neurons. The major protein constituents are myelin basic protein (MBP) and proteolipid protein (PLP). MBP, a peripheral membrane protein found in both the central and peripheral nervous systems (see Figure 22-15), has seven RNA splicing variants that encode different forms of the protein. It is synthesized by ribosomes located in the growing myelin sheath, an example of specific transport of mRNAs to a peripheral cell region. The localization of MBP mRNA depends on microtubules.

 Damage to proteins produced by oligodendrocytes underlies a prevalent human neurological disease, multiple sclerosis (MS). MS is usually characterized by spasms and weakness in one or more limbs, bladder dysfunction, local sensory losses, and visual disturbances. This disorder—the prototype *demyelinating disease*—is caused by patchy loss of myelin in areas of the brain and spinal cord. In MS patients, conduction of action potentials by the demyelinated neurons is slowed, and the Na^+ channels spread outward from the nodes, lowering their nodal concentration. The cause of the disease is not known but appears to involve either the body's

(a) Central nervous system glia

(b) Peripheral nervous system glia

FIGURE 22-14 Three types of glial cells. (a) A single oligodendrocyte in the central nervous system can myelinate segments of multiple axons. Astrocytes interact with neurons but do not form myelin. (b) Each Schwann cell insulates a section of a single peripheral nervous

system axon. [From B. Stevens, 2003, *Curr. Biol.* **13**:469, and adapted from D. L. Sherman and P. Brophy, 2005, *Nature Rev. Neurosci.* **6**:683–690. Photos: Courtesy of Varsha Shukla and Doug Field from NIH.]

production of auto-antibodies (antibodies that bind to normal body proteins) that react with MBP, or the secretion of proteases that destroy myelin proteins. A mouse mutant, *shiverer*, has a deletion of much of the MBP gene, leading to tremors, convulsions, and early death. Similarly, human (Pelizaeus-Merzbacher disease) and mouse (*jimpy*) mutations in the gene coding for the other major protein of CNS myelin, PLP, cause loss of oligodendrocytes and inadequate myelination. ■

Schwann Cells Schwann cells form myelin sheaths around peripheral nerves. A Schwann cell myelin sheath is a remarkable spiral wrap (Figure 22-14b). A long axon can have as many as several hundred Schwann cells along its length, each contributing myelin insulation to an *internode* stretch of about 1–1.5 μm of axon. For reasons that are not understood,

not all axons are myelinated. Mutations in mice that eliminate Schwann cells cause the death of most neurons.

In contrast to oligodendrocytes, each Schwann cell myelinates only one axon. The sheaths are composed of about 70 percent lipid (rich in cholesterol) and 30 percent protein. In the PNS, the principal protein constituent (~80 percent) of myelin is called protein 0 (P_0), an integral membrane protein that has immunoglobulin (Ig) domains. MBP is also an abundant component. The extracellular Ig domains of P_0 bind together the surfaces of sequential wraps around the axon to compact the spiral of myelin sheath (Figure 22-15). Other proteins play this kind of role in the CNS.

■ In humans, peripheral myelin, like CNS myelin, is a target of autoimmune disease, mainly involving the

FIGURE 22-15 Formation and structure of a myelin sheath in the peripheral nervous system. (a) At high magnification the specialized spiral myelin membrane appears as a series of layers, or lamellae, of phospholipid bilayers wrapped around the axon. (b) Close-up view of three layers of the myelin membrane spiral. The two most abundant integral myelin membrane proteins, P_0 and PMP22, are produced only by Schwann cells. The exoplasmic domain of a P_0 protein, which has an immunoglobulin fold, associates with similar domains emanating from P_0 proteins in the opposite membrane surface, thereby “zippering” together the exoplasmic membrane surfaces in close apposition.

These interactions are stabilized by binding of a tryptophan residue on the tip of the exoplasmic domain to lipids in the opposite membrane. Close apposition of the cytosolic faces of the membrane may result from binding of the cytosolic tail of each P_0 protein to phospholipids in the opposite membrane. PMP22 may also contribute to membrane compaction. Myelin basic protein (MBP), a cytosolic protein, remains between the closely apposed membranes as the cytosol is squeezed out. [Part (a) © Science VU/C. Raine/Visuals Unlimited; part (b) adapted from L. Shapiro et al., 1996, *Neuron* **17**: 435, and E. J. Arroyo and S. S. Scherer, 2000, *Histochem. Cell Biol.* **113**:1.]

formation of antibodies against P_0 . The Guillain-Barre syndrome (GBS), also known as *acute inflammatory demyelinating polyneuropathy*, is one such disease. GBS is the most common cause of rapid-onset paralysis, occurring at a frequency of 10^{-5} . The cause is unknown. The common inherited neurological disorder called *Charcot-Marie-Tooth disease*, which damages peripheral motor and sensory nerve function, is due to overexpression of the gene that encodes PMP22 protein, another constituent of peripheral nerve myelin. ■

Interactions between glia and neurons control the placement and spacing of myelin sheaths, and the assembly of nerve-transmission machinery at the nodes of Ranvier. Voltage-gated Na^+ channels and Na^+/K^+ pumps, for example, congregate at the nodes of Ranvier through interactions with cytoskeletal proteins. While the details of the node assembly process are not fully understood, a number of key players have been identified. In the PNS, where the process has been most studied, surface adhesion molecules in the Schwann cell membrane first interact with neuronal surface adhesion molecules. An immunoglobulin cell-adhesion molecule (IgCAM) in the glial membrane, called *neurofascin155*, contacts two axonal proteins, contactin and contactin-associated protein, at the edge of the node. These cell-cell contact events create boundaries at each side of the node.

The channel proteins and other molecules that will accumulate at the node are initially dispersed throughout the axons. Then axonal proteins, including two IgCAMs called *NrCAM* and *neurofascin186*, as well as ankyrin G (Chapter 17),

accumulate within the node. The two IgCAMs bind to a single transmembrane domain protein called *gliomedin* that is expressed in the glial cell. Experiments that eliminated gliomedin production showed that without it nodes do not form, so it is a key regulator. Ankyrin in the node contacts β IV spectrin, a major constituent of the cytoskeleton, thus tethering the node's protein complex to the cytoskeleton. Na^+ channels become associated with neurofascin186, NrCAM, and ankyrin G, firmly trapping the channel in the nodal segment of the axonal plasma membrane where it is needed. As a result of these multiple protein-protein interactions, the concentration of Na^+ channels is roughly a hundredfold higher in the nodal membrane of myelinated axons than in the axonal membrane of nonmyelinated neurons.

KEY CONCEPTS of Section 22.2

Voltage-Gated Ion Channels and the Propagation of Action Potentials

- Action potentials are sudden membrane depolarizations followed by rapid repolarization.
- An action potential results from the sequential opening and closing of voltage-gated Na^+ and K^+ channels in the plasma membrane of neurons and muscle cells (excitable cells; see Figure 22-7).

- Opening of voltage-gated Na^+ channels permits influx of Na^+ ions for about 1 ms, causing a sudden large depolarization of a segment of the membrane. The channels then close and become unable to open (refractory period) for several milliseconds, preventing further Na^+ flow (see Figure 22-7).
- As the action potential reaches its peak, opening of voltage-gated K^+ channels permits efflux of K^+ ions, which repolarizes and then hyperpolarizes the membrane. As these channels close, the membrane returns to its resting potential (see Figures 22-2 and 22-6).
- The excess cytosolic cations associated with an action potential generated at one point on an axon spread passively to the adjacent segment, triggering opening of voltage-gated Na^+ channels in the vicinity and thus propagation of the action potential along the axon.
- Because of the absolute refractory period of the voltage-gated Na^+ channels and the brief hyperpolarization resulting from K^+ efflux, the action potential is propagated in one direction only, toward the axon termini (see Figure 22-9).
- Voltage-gated Na^+ and Ca^{2+} channels are monomeric proteins containing four domains that are structurally and functionally similar to each of the subunits in the tetrameric voltage-gated K^+ channels. Each domain or subunit in voltage-gated cation channels contains six transmembrane α helices and a nonhelical P segment that forms the ion-selectivity pore (see Figure 22-10).
- Opening of voltage-gated channels results from movement of the positively charged S1–S4 paddles toward the extracellular side of the membrane in response to a depolarization of sufficient magnitude (see Figure 22-11).
- Closing and inactivation of voltage-gated cation channels result from movement of a cytosolic “ball” segment into the open pore (see Figure 22-12a).
- Myelination, which increases the rate of impulse conduction up to a hundredfold, permits the close packing of neurons characteristic of vertebrate brains.
- In myelinated neurons, voltage-gated Na^+ channels are concentrated at the nodes of Ranvier. Depolarization at one node spreads rapidly with little attenuation to the next node, so that the action potential jumps from node to node (see Figure 22-13).
- Myelin sheaths are produced by glial cells that wrap themselves in spirals around neurons. Oligodendrocytes produce myelin for the CNS; Schwann cells, for the PNS (see Figure 22-14).

22.3 Communication at Synapses

As we have discussed, electrical pulses transmit signals along neurons, but signals are transmitted between neurons and other excitable cells mainly by chemical signals. Synapses are the junctions where *presynaptic* neurons release these chemical signals, or neurotransmitters, which then act on *postsynaptic*

target cells (Figure 22-3). A target cell may be another neuron, a muscle, or a gland cell. Communication at chemical synapses usually goes in only one direction: pre- to postsynaptic cell.

Arrival of an action potential at an axon terminus in a presynaptic cell leads to opening of voltage-sensitive Ca^{2+} plasma membrane channels and an influx of Ca^{2+} , causing a localized rise in the cytosolic Ca^{2+} concentration in the axon terminus. In turn, the rise in Ca^{2+} triggers fusion of small (40–50 nm) neurotransmitter-containing synaptic vesicles with the plasma membrane, releasing neurotransmitters into the synaptic cleft, the narrow space separating the presynaptic from the postsynaptic cell. The membrane of the postsynaptic cell is located within approximately 50 nm of the presynaptic membrane, reducing the distance the neurotransmitter must diffuse.

Neurotransmitters—small, water-soluble molecules such as acetylcholine or dopamine—bind to receptors on the postsynaptic cell that, in turn, induce localized changes in the potential across its plasma membrane. If the membrane potential becomes less negative—that is, becomes depolarized—an action potential will tend to be induced in the postsynaptic cell. Such synapses are **excitatory**, and in general involve the opening of Na^+ channels in the postsynaptic plasma membrane. In contrast, in an **inhibitory synapse**, binding of the neurotransmitter to a receptor on the postsynaptic cell causes hyperpolarization of the plasma membrane—generation of a more inside-negative potential. Typically, hyperpolarization is the result of opening of Cl^- or K^+ channels in the postsynaptic plasma membrane, which tends to hinder generation of an action potential.

Neurotransmitter receptors fall into two broad classes: ligand-gated ion channels, which open immediately upon neurotransmitter binding, and G protein-coupled receptors (GPCRs). Neurotransmitter binding to a GPCR induces the opening or closing of a *separate* ion-channel protein over a period of seconds to minutes. These “slow” neurotransmitter receptors were discussed in Chapter 15 along with GPCRs that bind different types of ligands and modulate the activity of cytosolic proteins other than ion channels. Here we examine the structure and operation of the excitatory *nicotinic acetylcholine receptor* found at many nerve-muscle synapses. It was the first ligand-gated ion channel to be purified, cloned, and characterized at the molecular level, and provides a paradigm for other neurotransmitter-gated ion channels.

The duration of the neurotransmitter signal depends on the amount of transmitter released by the presynaptic cell, which in turn depends on the amount of transmitter that had been stored as well as the frequency of action potentials arriving at the synapse. The duration of the signal also depends on how rapidly any unbound neurotransmitter is degraded in the synaptic cleft or transported back into the presynaptic cell. Presynaptic cell plasma membranes, as well as glia, contain transporter proteins that pump neurotransmitters across the plasma membrane back into the cell, thus keeping the extracellular concentrations of transmitter low.

In this section we focus first on how synapses form and how they control the regulated secretion of neurotransmitters

FIGURE 22-16 Synaptic vesicles in the axon terminus near the region where neurotransmitter is released. In this longitudinal section through a neuromuscular junction, the basal lamina lies in the synaptic cleft separating the neuron from the muscle membrane, which is extensively folded. Acetylcholine receptors are concentrated in the postsynaptic muscle membrane at the top and part way down the sides of the folds in the membrane. A Schwann cell surrounds the axon terminus. [From J. E. Heuser and T. Reese, 1977, in E. R. Kandel, ed., *The Nervous System*, vol. 1, *Handbook of Physiology*, Williams and Wilkins, p. 266.]

in the context of the basic principles of vesicular trafficking outlined in Chapter 14. Next we look at the mechanisms that limit the duration of the synaptic signal, and how neurotransmitters are received and interpreted by the postsynaptic cell.

Formation of Synapses Requires Assembly of Presynaptic and Postsynaptic Structures

Axons extend from the cell body during development, guided by signals from other cells along the way so that the axon termini will reach the correct location (see Section 18.8). As axons grow, they come into contact with their potential target cells, such as dendrites of other neurons, and often at such sites synapses form. In the CNS, synapses with presynaptic specializations occur frequently all along an axon; in contrast, motor neurons form synapses with muscle cells only at the axon termini.

Neurons cultured in isolation will not form synapses very efficiently, but when glia are added, the rate of synapse formation increases substantially. Astrocytes and Schwann cells send protein signals to neurons to stimulate the formation of synapses and then help to preserve them. One such signal is thrombospondin (TSP), a component of the extracellular matrix; mice lacking two *thrombospondin* genes have only 70 percent of the normal number of synapses in their brains. Mutual communication between neurons and the glia that surround them is frequent and complex, making the signals and information they carry an area of active research. There is also evidence that neurons form synapses on glia. While glia do not produce action potentials, they do have complex arrays of channels and ion fluxes.

At the site of a synapse, the presynaptic cell has hundreds to thousands of synaptic vesicles, some docked at the membrane

and others waiting in reserve. The release of neurotransmitter into the synaptic cleft occurs in the *active zone*, a specialized region of the plasma membrane containing a remarkable assemblage of proteins whose functions include modifying the properties of the synaptic vesicles and bringing them into position for docking and fusing with the plasma membrane. Viewed by electron microscopy, the active zone has electron-dense material and fine cytoskeletal filaments (Figure 22-16). A similarly dense region of specialized structures is seen across the synapse in the postsynaptic cell, the *postsynaptic density* (PSD). Cell-adhesion molecules that connect pre- and postsynaptic cells keep the active zone and PSD aligned. After release of synaptic vesicles in response to an action potential, the presynaptic neuron retrieves synaptic vesicle membrane proteins by *endocytosis* both within and outside the active zone.

Synapse assembly has been extensively studied at the *neuromuscular junction* (NMJ) (Figure 22-17). At these synapses acetylcholine is the neurotransmitter produced by motor neurons, and its receptor, AChR, is produced by the postsynaptic muscle cell. Muscle cell precursors, myoblasts, put into culture will spontaneously fuse into multinucleate myotubes that look similar to normal muscle cells. As myotubes form, AChR is produced near the center of the cell and inserted into the myotube plasma membrane, forming diffuse membrane patches (Figure 22-17a).

The formation of the neuromuscular synapse is a multi-step process requiring signaling interactions between motor neurons and muscle fibers. A key player is MuSK, a receptor tyrosine kinase that is localized in the diffuse AChR-rich patches of the myotube plasma membrane. In ways that are not known, MuSK both induces clustering of AChRs and serves to attract the termini of growing motor neuron axons. For example, knockdown of MuSK inhibits both processes, while overexpression of MuSK in cultured muscle cells induces motor neuron growth throughout the muscle and formation of excess synapses.

Another key player is *Agrin*, a glycoprotein synthesized by developing motor neurons, transported in vesicles along axon microtubules, and secreted near the developing myotubes. Agrin binds to LRP4, a single-pass membrane-spanning protein; this stimulates an association between LRP4 and MuSK and increases MuSK kinase activity (Figure 22-17b). This leads to activation of several downstream signal transduction pathways, one of which leads to activation of Rac and Rho (see Section 17.3) and formation of clusters of

FIGURE 22-17 Formation of the neuromuscular junction

(a) Motor neuron-myotube interactions. Following fusion of myoblasts to form multinucleate myotubes, the nuclei synthesize acetylcholine receptor (AChR) mRNA. The nuclei near the center of each muscle fiber synthesize significantly more AChR mRNA than other nuclei. AChRs together with MuSK receptor kinases accumulate in membrane patches near the center of the cell, the prospective synaptic region of the muscle, prior to and independent of innervation; the cell is said to be “prepatterned.” The motor neuron axon termini grow toward these AChR clusters and secrete the glycoprotein Agrin. Agrin, in turn, induces clustering of the AChRs (dark red) and MuSKs around the axon termini (green), forming the neuromuscular junction. (Inset) Micrograph of a synapse from a postnatal (3-week-old) mouse, viewed by staining for axons (neurofilament) and synaptic vesicles (synaptophysin), shown together in green, and AChRs, shown in red. (b) Signaling downstream of Agrin receptors. Motor axons secrete Agrin, which stabilizes postsynaptic differentiation by binding LRP4 and activating MuSK kinase activity. Phosphorylation of tyrosines in the MuSK juxta-membrane region, indicated by yellow P in circle, stimulates recruitment and tyrosine phosphorylation of Dok-7, an adaptor protein that is expressed selectively in muscle, which forms a dimer, stimulates MuSK kinase activity, and recruits the adapter protein Crk/Crk-L. Crk/Crk-L is essential to activate a Rac/Rho- and Rapsyn-dependent pathway for clustering AChRs opposite the presynaptic axon termini; this pathway involves several cytoskeletal proteins including actin and myosins. The pathway for synapse-specific transcription is less well understood but likely involves JNK kinase-dependent activation of ETS-family transcription factors that stimulate expression of multiple genes encoding synaptic proteins such as acetylcholine receptors, MuSK, LRP4, and acetylcholinesterase (AChE), the extracellular enzyme that localizes to the synaptic cleft and that degrades acetylcholine to choline and acetate. [Micrograph from Herbst, R. et al., 2002, *Development*, 129:5449–5460.]

AChRs with the cytoskeletal protein rapsyn; this interaction, together with binding of other cytoskeletal proteins including actin, leads to localization of AChRs opposite the nerve termini at the neuromuscular junction. The density of acetylcholine receptors in a mature synapse reaches $\sim 10,000$ – $20,000/\mu\text{m}^2$, while elsewhere in the plasma membrane the density is $\sim 10/\mu\text{m}^2$. Another pathway, also not well understood, leads to activation of ETS-family transcription factors and stimulation of expression of multiple genes encoding synaptic proteins such as rapsyn and AChRs.

Neurotransmitters Are Transported into Synaptic Vesicles by H^+ -Linked Antiport Proteins

In this section, we focus on how neurotransmitters are packaged in membrane-bound *synaptic vesicles* in the axon terminus. Numerous small molecules function as neurotransmitters at various synapses. With the exception of acetylcholine, the neurotransmitters shown in Figure 22-18 are amino acids or derivatives of amino acids. Nucleotides such as ATP and the corresponding nucleosides, which lack phosphate groups, also

function as neurotransmitters. Each neuron generally produces just one type of neurotransmitter. While the types of neurotransmitters are varied and while they operate in different parts of the nervous system, all signaling by neurotransmitters results in one of two outcomes: either the transmission of an electrical signal, or its inhibition.

All of these neurotransmitters are synthesized in the cytosol and imported into membrane-bound synaptic vesicles within axon termini, where they are stored. These vesicles are 40–50 nm in diameter, and their lumen has a low pH, generated

γ -Aminobutyric acid, or GABA
(derived from glutamate)

FIGURE 22-18 Structures of several small molecules that function as neurotransmitters. Except for acetylcholine, all these are amino acids (glycine and glutamate) or derived from the indicated amino acids. The three transmitters synthesized from tyrosine, which contain the catechol moiety (blue highlight), are referred to as *catecholamines*.

by operation of a V-class proton pump in the vesicle membrane. Similar to the accumulation of metabolites in plant vacuoles (see Figure 11-29), this proton concentration gradient (vesicle lumen > cytosol) powers neurotransmitter import by ligand-specific H^+ -linked neurotransmitter antiporters in the vesicle membrane (Figure 22-19).

For example, acetylcholine is synthesized in the cytosol from acetyl coenzyme A (acetyl CoA), an intermediate in the degradation of glucose and fatty acids, and choline in a reaction catalyzed by choline acetyltransferase:

Synaptic vesicles take up and concentrate acetylcholine from the cytosol against a steep concentration gradient, using an H^+ /acetylcholine antiporter in the vesicle membrane; as with other antiporters, the export of protons from the forming vesicle down its electrochemical gradient powers the uptake of the neurotransmitter. Curiously, the gene encoding this antiporter is contained entirely within the first intron of the gene encoding choline acetyltransferase, a mechanism conserved throughout evolution for ensuring coordinate expression of these two proteins.

Different H^+ /neurotransmitter antiport proteins are used for import of other neurotransmitters into synaptic vesicles. For example, glutamate is imported into synaptic vesicles by proteins called *vesicular glutamate transporters (VGLUTs)*. VGLUTs are highly specific for glutamate but have rather low substrate affinity ($K_m = 1\text{--}3\text{ mM}$). Like the acetylcholine transporter, VGLUTs are antiporters, moving glutamate into synaptic vesicles while protons move in the other direction.

Synaptic Vesicles Loaded with Neurotransmitter Are Localized near the Plasma Membrane

A highly organized arrangement of cytoskeletal fibers in the axon terminus helps localize synaptic vesicles in the active zone. The vesicles themselves are linked together by *synapsin*, a fibrous phosphoprotein associated with the cytosolic surface of all synaptic vesicle membranes. Filaments of synapsin also radiate from the plasma membrane and bind to

FIGURE 22-19 Cycling of neurotransmitters and of synaptic vesicles in axon termini. Most synaptic vesicles are formed by endocytic recycling as depicted here. The entire cycle typically takes about 60 seconds. **Step 1:** The uncoated vesicles express a V-type proton pump (orange) and a single type of H^+ -neurotransmitter antiporter (blue) specific for the particular neurotransmitter, to import neurotransmitters (red dots) from the cytosol. **Step 2:** Synaptic vesicles loaded with neurotransmitter move to the active zone. **Step 3:** Vesicles dock at defined sites on the plasma membrane of the presynaptic cell, and the vesicle v-SNAREs called VAMP bind to the plasma membrane t-SNAREs, forming a SNARE complex. Synaptotagmin prevents membrane fusion and release of neurotransmitter. Botulinum toxin prevents exocytosis by proteolytically cleaving VAMP, the v-SNARE on vesicles. **Step 4:** In response to a nerve impulse (action potential), voltage-gated Ca^{2+} channels in the plasma membrane open, allowing an influx of Ca^{2+} from the extracellular medium. The resulting Ca^{2+} -induced confor-

mational change in synaptotagmin leads to fusion of docked vesicles with the plasma membrane and release of neurotransmitters into the synaptic cleft. Synaptotagmin does not participate in the later steps of vesicle recycling or neurotransmitter import though it is still present. **Step 5:** Na^+ symporter proteins take up neurotransmitter from the synaptic cleft into the cytosol, which limits the duration of the action potential and partially recharges the cell with transmitter. **Step 6:** Vesicles are recovered by endocytosis, creating uncoated vesicles, ready to be refilled and begin the cycle anew. After clathrin/AP vesicles containing v-SNARE and neurotransmitter transporter proteins bud inward and are pinched off in a dynamin-mediated process, they lose their coat proteins. Dynamin mutations such as shibire in *Drosophila* block the re-formation of synaptic vesicles, leading to paralysis. Unlike most neurotransmitters, acetylcholine is not recycled. [See K. Takei et al., 1996, *J. Cell Biol.* **133**:1237; V. Murthy and C. Stevens, 1998, *Nature* **392**:497; and R. Jahn et al., 2003, *Cell* **112**:519.]

vesicle-associated synapsin. These interactions probably keep synaptic vesicles close to the part of the plasma membrane facing the synapse. Indeed, synapsin knockout mice, although viable, are prone to seizures; during repetitive stimulation of many neurons in such mice, the number of synaptic vesicles that fuse with the plasma membrane is greatly reduced. Thus synapsins are thought to recruit synaptic vesicles to the active zone.

Influx of Ca^{2+} Triggers Release of Neurotransmitters

The exocytosis of neurotransmitters from synaptic vesicles involves vesicle-targeting and fusion events similar to those that occur during the intracellular transport of secreted and plasma-membrane proteins (Chapter 14). However, two unique features critical to synapse function differ from other

secretory pathways: (1) secretion is tightly coupled to arrival of an action potential at the axon terminus, and (2) synaptic vesicles are recycled locally to the axon terminus after fusion with the plasma membrane. Figure 22-19 shows the entire cycle whereby synaptic vesicles are filled with neurotransmitter, release their contents, and are recycled.

Depolarization of the plasma membrane cannot, by itself, cause synaptic vesicles to fuse with the plasma membrane. In order to trigger vesicle fusion, an action potential must be converted into a chemical signal—namely, a localized rise in the cytosolic Ca^{2+} concentration. The transducers of the electrical signals are *voltage-gated Ca^{2+} channels* localized to the region of the plasma membrane adjacent to the synaptic vesicles. The membrane depolarization due to arrival of an action potential opens these channels, permitting an influx of Ca^{2+} ions from the extracellular medium into the region of the axon terminus near the docked synaptic vesicles. Importantly, the rise in cytosolic Ca^{2+} is localized; it is also transient, as the excess Ca^{2+} is rapidly pumped out of the cell by plasma membrane Ca^{2+} pumps.

A simple experiment demonstrates the importance of voltage-gated Ca^{2+} channels in release of neurotransmitters. A preparation of neurons in a Ca^{2+} -containing medium is treated with tetrodotoxin, a drug that blocks voltage-gated Na^{+} channels and thus prevents conduction of action potentials. As expected, no neurotransmitters are secreted into the culture medium. If the axonal membrane is then artificially depolarized, by making the medium ~ 100 mM KCl, in the presence of extracellular Ca^{2+} , neurotransmitters are released from the cells because of the influx of Ca^{2+} through open voltage-gated Ca^{2+} channels. Indeed, patch-clamping experiments show that voltage-gated Ca^{2+} channels, like voltage-gated Na^{+} channels, open transiently upon depolarization of the membrane.

Two pools of neurotransmitter-filled synaptic vesicles are present in axon termini: those docked at the plasma membrane, which can be readily exocytosed, and the great majority that are in reserve in the active zone near the plasma membrane. Each rise in Ca^{2+} generated by arrival of a single action potential triggers exocytosis of about 10 percent of the docked vesicles. Membrane proteins unique to synaptic vesicles then are specifically internalized by endocytosis, usually via the same types of clathrin-coated vesicles used to recover other plasma-membrane proteins by other types of cells. After the endocytosed vesicles lose their clathrin coat, they are rapidly refilled with neurotransmitter. The ability of many neurons to fire 50 times a second is clear evidence that the recycling of vesicle membrane proteins occurs quite rapidly. The machinery of endocytosis and exocytosis is highly conserved, and is described in more detail in Chapter 14.

A Calcium-Binding Protein Regulates Fusion of Synaptic Vesicles with the Plasma Membrane

Fusion of synaptic vesicles with the plasma membrane of axon termini depends on SNAREs, the same type of proteins that mediate membrane fusion of other regulated secretory vesicles. The

principal v-SNARE in synaptic vesicles (VAMP) tightly binds syntaxin and SNAP-25, the principal t-SNAREs in the plasma membrane of axon termini, to form four-helix SNARE complexes. After fusion, SNAP proteins and NSF within the axon terminus promote disassociation of VAMP from t-SNAREs, as in the fusion of secretory vesicles depicted in Figure 14-10.

 Strong evidence for the role of VAMP in neurotransmitter exocytosis is provided by the mechanism of action of botulinum toxin, a bacterial protein that can cause the paralysis and death characteristic of *botulism*, a type of food poisoning. The toxin is composed of two polypeptides: One binds to motor neurons that release acetylcholine at synapses with muscle cells, facilitating entry of the other polypeptide, a protease, into the cytosol of the axon terminus. The only protein this protease cleaves is VAMP (see Figure 22-19, step 3). After the botulinum protease enters an axon terminus, synaptic vesicles that are not already docked rapidly lose their ability to fuse with the plasma membrane because cleavage of VAMP prevents assembly of SNARE complexes. The resulting block in acetylcholine release at neuromuscular synapses causes paralysis. However, vesicles that are already docked exhibit remarkable resistance to the toxin, indicating that SNARE complexes may already be in a partially assembled, protease-resistant state when vesicles are docked on the presynaptic membrane. ■

The signal that triggers exocytosis of docked synaptic vesicles is a very localized rise in the Ca^{2+} concentration in the cytosol near vesicles from $0.1 \mu\text{M}$, characteristic of resting cells, to $1\text{--}100 \mu\text{M}$ following arrival of an action potential in stimulated cells. The speed with which synaptic vesicles fuse with the presynaptic membrane after a rise in cytosolic Ca^{2+} (less than 1 ms) indicates that the fusion machinery is entirely assembled in the resting state and can rapidly undergo a conformational change leading to exocytosis of neurotransmitter (Figure 22-20). A Ca^{2+} -binding protein called *synaptotagmin*, located in the membrane of synaptic vesicles, is a key component of the vesicle-fusion machinery that triggers exocytosis in response to Ca^{2+} . A protein called complexin is thought to bind to the α -helical bundle of an assembled v-SNARE/t-SNARE complex that bridges the synaptic vesicle and plasma membranes, preventing the final fusion step. Binding of Ca^{2+} to synaptotagmin relieves this inhibition, releasing complexin and allowing the fusion event to occur very rapidly. While the mechanisms by which synaptotagmin functions are debated, Figure 22-20 depicts a widely accepted model.

Several lines of evidence support a role for synaptotagmin as the Ca^{2+} sensor for exocytosis of neurotransmitters. Mutant embryos of *Drosophila* and *C. elegans* that completely lack synaptotagmin fail to hatch and exhibit very reduced, uncoordinated muscle contractions. Larvae with partial loss-of-function mutations of synaptotagmin survive, but their neurons are defective in Ca^{2+} -stimulated vesicle exocytosis. Moreover, in mice, mutations in synaptotagmin that decrease its affinity for Ca^{2+} cause a corresponding increase in the amount of cytosolic Ca^{2+} needed to trigger rapid exocytosis.

FIGURE 22-20 Synaptotagmin-mediated fusion of synaptic vesicles with the plasma membrane. Only a few synaptic vesicles are docked at the presynaptic plasma membrane; these are primed for fusion with the plasma membrane. The tight interconnections between the synaptic vesicle and plasma membrane are mediated in part by bundles of four α helices derived from complexes of vesicle v-SNARE and plasma membrane t-SNARE proteins (see Figure 14-10). The fusion of the two membranes is prevented by binding of complexin protein to the v-SNARE/t-SNARE complex. Synaptotagmin is composed of a short intraluminal sequence, a single transmembrane α helix that anchors it in the synaptic vesicle membrane, a linker, and two Ca^{2+} -binding domains termed C2A and C2B. Synaptotagmin without bound Ca^{2+} may also bind to the v-SNARE/t-SNARE complex and prevent membrane fusion. A localized rise in Ca^{2+} allows Ca^{2+} ions to bind to synaptotagmin, altering its three-dimensional conformation. This triggers release of the complexin fusion inhibitor, binding (or altered binding) of synaptotagmin to the v-SNARE/t-SNARE complex, instantaneous membrane fusion, and release of neurotransmitters into the extracellular space. [After T. Südhof and J. Rothman, 2009, *Science* 323:474.]

Fly Mutants Lacking Dynamin Cannot Recycle Synaptic Vesicles

Synaptic vesicles are formed primarily by endocytic budding from the plasma membrane of axon termini. Endocytosis usually involves clathrin-coated pits and is quite specific, in that several membrane proteins unique to the synaptic vesicles (e.g., neurotransmitter transporters) are specifically incorporated into the endocytosed vesicles and resident plasma membrane proteins (e.g., the voltage-sensitive Ca^{2+} channel) remain. In this way, synaptic-vesicle membrane proteins can be reused and the recycled vesicles refilled with neurotransmitter (see Figure 22-19, step 6).

As in the formation of other clathrin/AP-coated vesicles, pinching off of endocytosed synaptic vesicles requires the

GTP-binding protein *dynamin* (see Figure 14-19). Indeed, analysis of a temperature-sensitive *Drosophila* mutant called *shibire* (*shi*), which encodes the fly dynamin protein, provided early evidence for the role of dynamin in endocytosis. At the permissive temperature of 20 °C, the mutant flies are normal, but at the nonpermissive temperature of 30 °C, they are paralyzed (*shibire*, “paralyzed,” in Japanese) because pinching off of clathrin-coated pits in neurons and other cells is blocked. When viewed in the electron microscope, the *shi* neurons at 30 °C show abundant clathrin-coated pits with long necks but few clathrin-coated vesicles. The appearance of nerve termini in *shi* mutants at the nonpermissive temperature is similar to that of termini from normal neurons incubated in the presence of a nonhydrolyzable analog of GTP (see Figure 14-20). Because of their inability to pinch off new synaptic vesicles, the neurons in *shi* mutants eventually become depleted of synaptic vesicles when flies are shifted to the nonpermissive temperature, leading to a cessation of synaptic signaling and to paralysis.

Signaling at Synapses Is Terminated by Degradation or Reuptake of Neurotransmitters

Following their release from a presynaptic cell, neurotransmitters must be removed or destroyed to prevent continued stimulation of the postsynaptic cell. Signaling can be terminated by diffusion of a transmitter away from the synaptic cleft, but this is a slow process. Instead, one of two more rapid mechanisms terminates the action of neurotransmitters at most synapses.

Signaling by acetylcholine is terminated when it is hydrolyzed to acetate and choline by *acetylcholinesterase*, an enzyme localized to the synaptic cleft. Choline released in this reaction is transported back into the presynaptic axon terminus by a Na^+ /choline symporter and used in synthesis of more acetylcholine. The operation of this transporter is similar to that of the Na^+ -linked symporters used to transport glucose into cells against a concentration gradient (see Figure 11-26).

With the exception of acetylcholine, all the neurotransmitters shown in Figure 22-18 are removed from the synaptic cleft by transport back into the axon termini that released them. Thus these transmitters are recycled intact, as depicted in Figure 22-19 (step 5). Transporters for GABA, norepinephrine, dopamine, and serotonin were the first to be cloned and studied. These four transport proteins are all Na^+ -linked symporters. They are 60–70 percent identical in their amino acid sequences, and each is thought to contain 12 transmembrane α helices. As with other Na^+ symporters, the movement of Na^+ into the cell down its electrochemical gradient provides the energy for uptake of the neurotransmitter. To maintain electroneutrality, Cl^- often is transported via an ion channel along with the Na^+ and neurotransmitter.

 Neurotransmitters and their transporters are targets of a variety of powerful and sometimes devastating drugs. Cocaine binds to and inhibits the transporters for norepinephrine, serotonin, and dopamine. In particular, binding of cocaine to the dopamine transporter inhibits reuptake

of dopamine, causing a higher-than-normal concentration of dopamine to remain in the synaptic cleft and prolonging the stimulation of postsynaptic neurons. Long-lasting exposure to cocaine, as occurs with habitual use, leads to down-regulation of dopamine receptors and thus altered regulation of dopaminergic signaling. It is thought that decreased dopaminergic signaling after chronic cocaine use may contribute to depressive mood disorders and sensitize important brain reward circuits to the reinforcing effects of cocaine, leading to addiction. Similarly, therapeutic agents such as the antidepressant drugs fluoxetine (Prozac) and imipramine block serotonin reuptake, and the tricyclic antidepressant desipramine blocks norepinephrine reuptake. As a result, these drugs also cause a higher-than-normal concentration of neurotransmitter to remain in the synaptic cleft and prolong the stimulation of postsynaptic neurons. Fluoxetine and similarly acting drugs such as paroxetine (Paxil) and sertraline (Zoloft) are often referred to collectively as selective serotonin reuptake inhibitors (SSRIs). ■

Opening of Acetylcholine-Gated Cation Channels Leads to Muscle Contraction

In this section we look at how binding of neurotransmitters by receptors on postsynaptic cells leads to changes in the cells' membrane potential, using the communication between motor neurons and muscles as an example. At these synapses, called neuromuscular junctions, acetylcholine is the neurotransmitter. A single axon terminus of a frog motor neuron may contain a million or more synaptic vesicles, each containing 1000–10,000 molecules of acetylcholine; these vesicles often accumulate in rows in the active zone (see Figures 22-16 and 22-17). Such a neuron can form synapses with a single skeletal muscle cell at several hundred points.

The nicotinic acetylcholine receptor, which is expressed in muscle cells, is a *ligand-gated channel* that admits both K^+ and Na^+ . These receptors are also produced in brain neurons and are important in learning and memory; acetylcholine receptor loss is observed in schizophrenia, epilepsy, drug addiction, and Alzheimer's disease. Antibodies against acetylcholine receptors constitute a major part of the autoimmune reactivity in the disease myasthenia gravis. The receptor is so named because it is bound by nicotine; it has been implicated in nicotine addiction in tobacco smokers. There are at least 14 different isoforms of the receptor, which assemble into homo- and heteropentamers with varied properties.

The effect of acetylcholine on this receptor can be determined by patch-clamping studies on isolated outside-out patches of muscle plasma membranes. Outside-out patch-clamping is a technique that measures the effects of extracellular solutes on channel receptors within the isolated patch (see Figure 11-22c). Such measurements have shown that acetylcholine causes opening of a cation channel in the receptor capable of transmitting 15,000–30,000 Na^+ and K^+ ions per millisecond. However, since the resting potential of the muscle plasma membrane is near E_K , the potassium equilibrium potential, opening of acetylcholine receptor channels causes little increase

FIGURE 22-21 Sequential activation of gated ion channels at a neuromuscular junction. Arrival of an action potential at the terminus of a presynaptic motor neuron induces opening of voltage-gated Ca^{2+} channels in the neuron (step 1) and subsequent release of acetylcholine, which triggers opening of the ligand-gated acetylcholine receptors in the muscle plasma membrane (step 2). The open receptor channel allows an influx of Na^+ and an efflux of K^+ from the muscle cell. The Na^+ influx produces a localized depolarization of the membrane, leading to opening of voltage-gated Na^+ channels and generation of an action potential (step 3). When the spreading depolarization reaches transverse tubules, it is sensed by voltage-gated Ca^{2+} channels in the plasma membrane. Through an unknown mechanism (indicated as ?) these channels remain closed but influence Ca^{2+} channels in the sarcoplasmic reticulum membrane (a network of membrane-bound compartments in muscle), which release stored Ca^{2+} into the cytosol (step 4). The resulting rise in cytosolic Ca^{2+} causes muscle contraction by mechanisms discussed in Chapter 17.

in the efflux of K^+ ions; Na^+ ions, on the other hand, flow into the muscle cell, driven by the Na^+ electrochemical gradient.

The simultaneous increase in permeability to Na^+ and K^+ ions following binding of acetylcholine produces a net depolarization to about -15 mV from the muscle resting potential of -85 to -90 mV. As shown in Figure 22-21, this localized depolarization of the muscle plasma membrane triggers opening of voltage-gated Na^+ channels, leading to generation and conduction of an action potential in the muscle cell surface membrane by the same mechanisms described previously for neurons. When the membrane depolarization reaches transverse tubules (see Figure 17-34), specialized invaginations of the plasma membrane, it acts on Ca^{2+} channels in the plasma membrane apparently without causing them to open. Somehow this causes opening of adjacent Ca^{2+} -release channels in the sarcoplasmic reticulum membrane. The subsequent flow of stored Ca^{2+} ions from the sarcoplasmic reticulum into the cytosol raises the cytosolic Ca^{2+} concentration sufficiently to induce muscle contraction.

Careful monitoring of the membrane potential of the muscle membrane at a synapse with a cholinergic motor neuron has demonstrated spontaneous, intermittent, and random ~2-ms depolarizations of about 0.5–1.0 mV in the absence of stimulation of the motor neuron. Each of these depolarizations is caused by the spontaneous release of acetylcholine from a single synaptic vesicle in the neuron. Indeed, demonstration of such spontaneous small depolarizations led to the notion of the quantal release of acetylcholine (later applied to other neurotransmitters) and thereby led to the hypothesis of vesicle exocytosis at synapses. The release of one acetylcholine-containing synaptic vesicle results in the opening of about 3000 ion channels in the postsynaptic membrane, far short of the number needed to reach the threshold depolarization that induces an action potential. Clearly, stimulation of muscle contraction by a motor neuron requires the nearly simultaneous release of acetylcholine from numerous synaptic vesicles.

All Five Subunits in the Nicotinic Acetylcholine Receptor Contribute to the Ion Channel

The acetylcholine receptor from skeletal muscle is a pentameric protein with a subunit composition of $\alpha_2\beta\gamma\delta$. These four different subunit types have considerable sequence homology with each other; on average, about 35–40 percent of the residues in any two subunits are similar. The complete receptor has five-fold symmetry, and the actual cation channel is a tapered central pore lined by homologous segments from each of the five subunits (Figure 22-22).

The channel opens when the receptor cooperatively binds two acetylcholine molecules to sites located at the interfaces of the $\alpha\delta$ and $\alpha\gamma$ subunits, as shown in Figure 22-22a. Once acetylcholine is bound to a receptor, the channel is opened within a few microseconds. Studies measuring the receptor's permeability to different small cations suggest that the open ion channel is, at its narrowest, about 0.65–0.80 nm in diameter, in agreement with estimates from electron micrographs. This would be sufficient to allow passage of both Na^+ and K^+ ions with their shell of bound water molecules.

Thus the acetylcholine receptor probably transports hydrated ions, unlike Na^+ and K^+ channels, both of which allow passage only of nonhydrated ions (see Figure 11-21).

The central ion channel is lined by five homologous transmembrane M2 α helices, one from each of the five subunits (see Figure 22-22c). The M2 helices are composed largely of hydrophobic or uncharged polar amino acids, but

FIGURE 22-22 Three-dimensional structure of the nicotinic acetylcholine receptor. Three-dimensional molecular structure of the *Torpedo* nicotinic acetylcholine receptor as viewed (a) from the synaptic cleft and (b) parallel to the plane of the membrane. For clarity, only the front two subunits, α and γ , are highlighted in (b) (colors: α , red; β , green; γ , blue; δ , light blue). The two acetylcholine-binding sites are located about 3 nm from the membrane surface and are highlighted in yellow; only the one at the $\alpha\gamma$ interface is shown in panel b. (c) Schematic cut-away model of the pentameric receptor in the membrane. Each subunit has four membrane-spanning α helices, M1–M4; the M2 α helix (red) faces the central pore. Aspartate and glutamate side chains form two rings of negative charges, one at each end of the M2 helices, that help exclude anions from and attract cations to the channel. The gate, which is opened by binding of acetylcholine, lies within the pore. [Parts (a) and (b) from N. Unwin, 2005, *J. Mol. Biol.* **346**:967–989.]

negatively charged aspartate or glutamate residues are located at each end, near the membrane faces, and several serine or threonine residues are near the middle. Mutant acetylcholine receptors in which a single negatively charged glutamate or aspartate in one M2 helix is replaced by a positively charged lysine have been expressed in frog oocytes. Patch-clamping measurements indicate that such altered proteins can function as channels, but the number of ions that pass through during the open state is reduced. The greater the number of glutamate or aspartate residues mutated (in one or multiple M2 helices), the greater the reduction in ion conductivity. These findings suggest that aspartate and glutamate residues form a ring of negative charges on the external surface of the pore that help to screen out anions and attract Na^+ or K^+ ions as they enter the channel. A similar ring of negative charges lining the cytosolic pore surface also helps select cations for passage.

The two acetylcholine-binding sites in the extracellular domain of the receptor lie $\sim 4\text{--}5$ nm from the membrane surface (see Figure 22-22b). Binding of acetylcholine thus must trigger conformational changes in the receptor subunits that can cause channel opening at some distance from the binding sites. Receptors in isolated postsynaptic membranes can be trapped in the open or closed state by rapid freezing in liquid nitrogen. Electron microscopic images of such preparations suggest that the five M2 helices rotate relative to the vertical axis of the channel during opening and closing.

We have discussed the neuromuscular junction as an excellent example of how neurotransmitters and their receptors work. Like acetylcholine, glutamate, a principal neurotransmitter in the vertebrate brain, uses two main types of receptors. One class, termed ionotropic glutamate receptors, are ligand-gated channels that allow the flow of K^+ , Na^+ , and sometimes Ca^{2+} in response to glutamate binding and that work along the same principles as AChR. Glutamate also binds to a second class of receptors, coupled to G proteins. Later in this chapter we will see how such G protein-coupled receptors (GPCRs) and ion channels function as receptors for odorants and tastants that activate various sensory nerve cells. To cover all of the neurotransmitter receptors, ion channels, and other signaling proteins that function in the brain would require a book much larger than this one!

Nerve Cells Make an All-or-None Decision to Generate an Action Potential

At the neuromuscular junction, virtually every action potential in the presynaptic motor neuron triggers an action potential in the postsynaptic muscle cell that propagates along the muscle fiber. The situation at synapses between neurons, especially those in the brain, is much more complex because the postsynaptic neuron commonly receives signals from many presynaptic neurons. The neurotransmitters released from presynaptic neurons may bind to an *excitatory receptor* on the postsynaptic neuron, thereby opening a channel that admits Na^+ ions or both Na^+ and K^+ ions. The acetylcholine and glutamate receptors just discussed are examples

of excitatory receptors, and opening of such ion channels leads to depolarization of the postsynaptic plasma membrane, promoting generation of an action potential. In contrast, binding of a neurotransmitter to an *inhibitory receptor* on the postsynaptic cell causes opening of K^+ or Cl^- channels, leading to an efflux of additional K^+ ions from the cytosol or an influx of Cl^- ions. In either case, the ion flow tends to hyperpolarize the plasma membrane, which inhibits generation of an action potential in the postsynaptic cell.

A single neuron can be affected simultaneously by signals received at multiple excitatory and inhibitory synapses. The neuron continuously integrates these signals and determines whether or not to generate an action potential. In this process, the various small depolarizations and hyperpolarizations generated at synapses move along the plasma membrane from the dendrites to the cell body and then to the axon hillock, where they are summed together. An action potential is generated whenever the membrane at the axon hillock becomes depolarized to a certain voltage, which can be different for different neurons, called the *threshold potential* (Figure 22-23). Thus an action potential is generated in an all-or-nothing fashion: depolarization to the threshold always leads to an action potential, whereas any depolarization that does not reach the threshold potential never induces it.

Whether a neuron generates an action potential in the axon hillock depends on the balance of the timing, amplitude, and localization of all the various inputs it receives; this signal computation differs for each type of neuron. In a sense, each neuron is a tiny analog-to-digital computer that averages all the receptor activations and electrical disturbances on its membrane (analog) and makes a decision whether or not (digital) to trigger an action potential and conduct it down the axon. An action potential will always have the same *magnitude* in any particular neuron. As we have noted, the *frequency* with which action potentials are generated in a particular neuron is the important parameter in its ability to signal other cells.

Gap Junctions Allow Certain Neurons to Communicate Directly

Chemical synapses employing neurotransmitters allow one-way communication at reasonably high speed. However, sometimes signals go from cell to cell electrically, without the intervention of chemical synapses. *Electrical synapses* depend on **gap junction** channels that link two cells together (Chapter 20). The effect of gap junction connections is to perfectly coordinate the activities of joined cells. An electrical synapse is *bidirectional*; either neuron can excite the other. Electrical synapses are common in the neocortex and thalamus, for example. The key feature of electrical synapses is their speed. While it takes about 0.5–5 ms for a signal to cross a chemical synapse, transmission across an electrical synapse is almost instantaneous, on the order of a fraction of a millisecond since the cytoplasm is continuous between the cells. In addition, the presynaptic cell (the one sending the signal) does not have to reach a threshold at which it can

EXPERIMENTAL FIGURE 22-23 Incoming signals must reach the threshold potential to trigger an action potential in a postsynaptic neuron. In this example, the presynaptic neuron is generating about one action potential every 4 ms. Arrival of each action potential at the synapse causes a small change in the membrane potential at the axon hillock of the postsynaptic neuron, in this example a depolarization of ~5 mV. When multiple stimuli cause the membrane of this postsynaptic cell to become depolarized to the threshold potential, here approximately 40 mV, an action potential is induced in it.

cause an action potential in the postsynaptic cell. Instead, any electrical current continues into the next cell and causes depolarization in proportion to the current.

An electrical synapse may contain thousands of gap channels, each composed of two hemichannels, one in each apposed cell. Gap junction channels in the neuron have a structure similar to conventional gap junctions (see Figure 20-20). Each hemichannel is an assembly of six copies of the connexin protein. Since there are about 20 mammalian connexin genes, diversity in channel structure and function can arise from the different protein components. The 1.6–2.0-nm channel itself allows the diffusion of molecules up to about 1,000 Da in size and has no trouble at all accommodating ions.

KEY CONCEPTS of Section 22.3

Communication at Synapses

- Synapses are the junctions between a presynaptic cell and a postsynaptic cell, and consist of small gaps (see Figure 22-3).
- Communication between presynaptic and postsynaptic cells is abundant as a synapse is being formed. Cell-adhesion molecules keep the cells aligned. At the neuromuscular junction, motor neurons induce the accumulation of acetylcholine receptors in the postsynaptic muscle plasma membrane close to the forming axon terminus (see Figure 22-17).
- In presynaptic cells, low-molecular-weight neurotransmitters (e.g., acetylcholine, dopamine, epinephrine) are imported from the cytosol into synaptic vesicles by H^+ -linked antiporters. V-class proton pumps maintain the low intravesicular pH that drives neurotransmitter import against a concentration gradient.

- Neurotransmitters (see Figure 22-18) are stored in hundreds to thousands of synaptic vesicles in the axon termini of the presynaptic cell (see Figure 22-16). When an action potential arrives there, voltage-sensitive Ca^{2+} channels open and the calcium causes synaptic vesicles to fuse with the plasma membrane, releasing neurotransmitter molecules into the synapse (see Figure 22-19, step 4).

- Neurotransmitters diffuse across the synapse and bind to receptors on the postsynaptic cell, which can be a neuron or a muscle. Chemical synapses of this sort are unidirectional (see Figure 22-3).

- Synaptic vesicles fuse with the plasma membrane using cellular machinery that is standard for exocytosis, including SNAREs, syntaxin, and SNAP proteins. Synaptotagmin protein is the calcium sensor that detects the action potential-stimulated rise in calcium that leads to the fusion (see Figure 22-20).

- Following neurotransmitter release from the presynaptic cell, vesicles are re-formed by endocytosis and recycled (see Figure 22-19, step 6).

- Dynamin, an endocytosis protein, is critical for the formation of new synaptic vesicles, probably specifically for the “pinching off” of inbound vesicles.

- Coordinated operation of four gated ion channels at the synapse of a motor neuron and a striated muscle cell leads to release of acetylcholine from the axon terminus, depolarization of the muscle membrane, generation of an action potential, and subsequent muscle contraction (see Figure 22-21).

- The nicotinic acetylcholine receptor, a ligand-gated cation channel, contains five subunits, each of which has a transmembrane α helix (M2) that lines the channel (see Figure 22-22).

- Neurotransmitter receptors fall into two classes: ligand-gated ion channels, which permit ion passage when open, and G protein-coupled receptors, which are linked to separate ion channels.
- A postsynaptic neuron generates an action potential only when the plasma membrane at the axon hillock is depolarized to the threshold potential by the summation of small depolarizations and hyperpolarizations caused by activation of multiple neuronal receptors (see Figure 22-23).
- Electrical synapses are direct, gap junction connections between neurons. Electrical synapses, unlike chemical synapses that employ neurotransmitters, are extremely fast in signal transmission and are bidirectional.

22.4 Sensing the Environment: Touch, Pain, Taste, and Smell

Our bodies are constantly receiving signals from our environment—light, sound, smells, tastes, mechanical stimulation, heat, and cold. In recent years dramatic progress has been made in understanding how our senses record impressions of the outside world, and how the brain processes that information. For example, in Chapter 15 we analyzed the functions of one of the two types of photoreceptors in the human retina, the *rods*, and learned how they serve as primary recipients of visual stimulation. Rods are stimulated by weak light, like moonlight, over a range of wavelengths, while the other photoreceptors, the *cones*, mediate color vision. These photoreceptors synapse on layer upon layer of interneurons that are innervated by different combinations of photoreceptor cells. These signals are processed and interpreted by the part of the brain called the *visual cortex*, where these nerve impulses are translated into an image of the world around us.

In this section we discuss the cellular and molecular mechanisms and specialized nerve cells underlying several of our other senses: touch and pain, taste, and smell. We see how two broad classes of receptors—ion channels and G protein-coupled receptors—function in these sensing processes. As with vision, multiple interneurons connect these sensory cells with the brain, where relayed signals are converted into perceptions of the environment. For the most part, we still do not fully understand how these neural subsystems are wired. However, in the case of smell, each sensory neuron expresses a single odorant receptor, and we shall see how multiple sensory neurons that express the same receptor activate the same brain center. The connections between odorant binding and perception by the brain are thus direct and fairly well understood.

Mechanoreceptors Are Gated Cation Channels

Our skin, especially the skin of our fingers, is highly specialized for collecting sensory information. Our whole body, in fact, has numerous **mechanosensors** embedded in its various tissues. These sensors frequently make us aware of touch, the

positions and movements of our limbs or head (proprioception), pain, and temperature, though we often go through periods when we ignore the inputs. Mammals use different sets of receptor cells to report on touch, temperature, and pain.

Many mechanosensory receptors are Na^+ or $\text{Na}^+/\text{Ca}^{2+}$ channels that are gated, or opened, in response to specific stimuli; activation of such receptors causes an influx of Na^+ or both Na^+ and Ca^{2+} ions, leading to membrane depolarization. Examples include the stretch and touch receptors that are activated by stretching of the cell membrane; these have been identified in a wide array of cells, ranging from vertebrate muscle and epithelial cells to yeast, plants, and even bacteria.

The cloning of genes encoding touch receptors began with the isolation of mutant strains of *Caenorhabditis elegans* that were insensitive to gentle body touching. Three of the genes in which mutations were isolated—*MEC4*, *MEC6*, and *MEC10*—encode three subunits of a Na^+ channel in the touch-receptor cells. Studies on worms with mutations in these genes showed that these channels are necessary for transduction of a gentle body touch; biophysical studies indicated that these channels likely open directly in response to mechanical stimulation (Figure 22-24). The touch-sensitive complexes contain several other proteins essential for touch sensitivity, including subunits of novel 15-protofilament microtubules in the cytosol and specific proteins in the extracellular matrix, but precisely how they affect channel function is not yet known. Similar kinds of channels are found in bacteria and lower eukaryotes; by opening in response to membrane stretching, these chan-

FIGURE 22-24 A molecular model of the MEC-4 touch-receptor complex in *C. elegans*. Mutations in any of the *MEC* genes can reduce or inactivate normal responses of the worm to a gentle body touch. The MEC-4 and MEC-10 proteins are the pore-forming subunits of the Na^+ channel; MEC-2 and MEC-6 are accessory subunits that enable channel activity. Mechanotransduction also requires a specialized extracellular matrix, consisting of MEC-5, a collagen isoform, and MEC-1 and MEC-9, both proteins with multiple EGF repeats. MEC-7 and MEC-12 are tubulin monomers that form novel 15-protofilament microtubules that are somehow also required for touch sensitivity. [After E. Lumpkin, K. Marshall, and A. Nelson, 2010, *J. Cell Biol.* **191**:237.]

nels may play a role in osmoregulation and the control of a constant cell volume.

A number of MEC-related molecules are expressed in mammalian neurons in the dorsal-root ganglia, and their roles in touch reception have been examined in knockout mice. For instance, disruption of the protein stomatin-like protein-3 (SLP3) causes defects in texture discrimination and loss of mechanosensitivity in a subset of mouse touch-receptor neurons.

Pain Receptors Are Also Gated Cation Channels

Animals as diverse as snails and humans sense noxious events (the process termed nociception); pain receptors, called **nociceptors**, respond to mechanical change, heat, and certain toxic chemicals. Pain serves to alert us to events such as tissue damage that are capable of producing injury and evokes behaviors that promote tissue healing. Persistent pain in response to tissue injury is common, and many individuals suffer from chronic pain. Thus, understanding both acute and chronic pain is a major research goal, as is the development of new types of drugs to treat pain.

One of the first mammalian pain receptors to be cloned and identified was TRPV1, a $\text{Na}^+/\text{Ca}^{2+}$ channel that is found in many sensory pain neurons of the peripheral nervous system and is activated by a wide variety of exogenous and endogenous physical and chemical stimuli. The best-known activators of TRPV1 are heat greater than 43 °C, acidic pH, and capsaicin, the molecule that makes chili peppers seem hot. Activation of TRPV1 receptors leads to painful, burning sensations. Numerous TRPV1 antagonists have been developed by pharmaceutical companies as possible pain medications. However, a major side effect that has limited the utility of these drugs is that they result in an elevation in body temperature; this suggests that one “normal” function of TRPV1 is to sense and regulate body temperature, and that the drugs inhibit this function.

Another pain-related gene that has attracted wide attention is *SCN9A*, which encodes a subunit of the voltage-gated Na^+ channel Nav1.7, which is expressed at high density in many pain-sensitive neurons. It is not clear what Nav1.7 directly senses, but humans homozygous for nonsense mutations in *SCN9A* are totally unable to sense pain although they are otherwise normal. This suggests that Nav1.7 is a vital component in the perception of pain in humans. Indeed, individuals with certain activating mutations in the *SCN9A* gene have severe episodic pain, and a common polymorphism in the *SCN9A* gene is correlated with pain perception in a variety of diseases. Thus drugs that modify the function of the Nav1.7 channel would also be potentially useful in treating a wide array of painful conditions.

Five Primary Tastes Are Sensed by Subsets of Cells in Each Taste Bud

We taste many chemicals, all of which are hydrophilic and nonvolatile molecules floating in saliva. All tastes are sensed on all areas of the tongue and selective cells respond preferentially to certain tastes. Like the other senses, that of taste likely

evolved to increase an animal's chance of survival. Many toxic substances taste bitter or acidic, and nourishing foods are broken down into molecules that taste sweet (e.g., sugars), salty, or umami (e.g., the meaty or savory taste of monosodium glutamate and other amino acids). Animals (including humans) can never be certain exactly what enters their mouth; the sense of taste enables an animal to make a quick decision—eat it, or get rid of it. Taste is less demanding of the nervous system than olfaction, because fewer types of molecules are monitored. What is impressive is the sensitivity of taste; bitter molecules can be detected at concentrations as low as 10^{-12} M.

There are receptors for salty, sweet, sour, umami, and bitter tastes in all parts of the tongue. The receptors are of two different types: channel proteins for salty and sour tastes and seven-transmembrane-domain proteins (G protein-coupled receptors) for sweetness, umami, and bitterness. Specific membrane receptors that detect fatty acids are present on taste bud cells, and fatty taste may come to be recognized as a sixth basic taste quality.

Taste buds are located in bumps in the tongue called *papillae*; each bud has a pore through which fluid carries solutes inside. Each taste bud has about 50–100 taste cells (Figure 22-25a, b), which are epithelial cells but with some of the functions of neurons. Microvilli on the taste cells' apical tips bear the taste receptors, directly contacting the external environment in the oral cavity and thus experiencing wide fluctuations in food-derived molecules as well as the presence of potentially harmful compounds. Cells in the tongue and other parts of the mouth are subjected to a lot of wear and tear, and taste bud cells are continuously replaced by cell divisions in the underlying epithelium. (A taste bud cell in rats has a lifetime of 10 days.)

Reception of a taste signal causes cell depolarization that triggers action potentials; these in turn cause Ca^{2+} uptake through voltage-dependent Ca^{2+} channels and release of neurotransmitters (Figure 22-25c–e). Taste cells do not grow axons; instead, they signal over short distances to adjacent neurons. What is not yet understood is how the brain interprets the input from nerves downstream of all of the taste buds and tells us exactly what we are tasting.

Bitter Taste Bitter tastants are diverse and are detected by a diverse family of about 25–30 different G protein-coupled receptors (GPCRs) known as T2Rs. As depicted in Figure 22-25c, all of these GPCRs activate a particular G_α isoform, called *gustducin*, that is expressed only in taste cells. However, it is the released ubiquitous $G_{\beta\gamma}$ subunit of the heterotrimeric G protein that binds to and activates a specific isoform of phospholipase C, which in turn generates IP_3 . IP_3 triggers Ca^{2+} release from the endoplasmic reticulum (see Figure 15-36). Ca^{2+} in turn binds to and opens a Ca^{2+} -gated Na^+ channel, TrpM5, leading to an influx of Na^+ and membrane depolarization. The combined action of elevated Ca^{2+} and membrane depolarization opens the large pores of an unusual membrane channel termed *Panx1*, resulting in release of ATP and probably other signaling molecules into the extracellular space. ATP stimulates the nerve cells that will ultimately carry the taste information to the brain.

FIGURE 22-25 The sense of taste. Panels (a) and (b) show a mammalian taste bud and its receptors. (a) The pink cells are the taste cells. These epithelial receptor cells contact the nerve cells (yellow). The chemical signals arrive at the microvilli seen at the top. (b) Micrograph of a taste bud, showing the receptor cells. The microvilli are barely visible at the top of the taste bud, indicated by the arrows. Panels (c) through (e) show the mechanisms by which five taste qualities are recognized and transduced in taste cells. (c) Sweet, bitter, and umami ligands bind specific taste GPCRs expressed in Type II receptor cells, activating a phosphoinositide pathway that elevates cytosolic Ca^{2+} . Ca^{2+} in turn binds to and opens a Ca^{2+} -gated Na^{+} channel, TrpM5, leading to an influx of Na^{+} and membrane depolarization. The combined action of elevated Ca^{2+} and membrane depolarization opens the large pores of an unusual membrane channel termed Pax1, resulting in release of ATP and probably other signaling molecules into the extracellular space. ATP and probably these other molecules stimulate

the nerve cells that will ultimately carry the information to the brain. (d) Salt is detected by direct permeation of Na^{+} ions through membrane ion channels, including the ENaC channel, directly depolarizing the plasma membrane. (e) Organic acids like acetic acid diffuse in their protonated form ($\text{H}\cdot\text{Ac}$) through the plasma membrane and dissociate into an anion and proton, acidifying the cytosol. Entry of strong acids like HCl is facilitated by a proton channel in the apical membrane of the sour-sensing cells that enables protons to reach the cytosol. Intracellular H^{+} is believed to block a proton-sensitive K^{+} channel (as yet unidentified) and thus depolarize the membrane. Voltage-gated Ca^{2+} channels would open, leading to an elevation in cytosolic Ca^{2+} that triggers exocytosis of synaptic vesicles that are not depicted. [Part (a) adapted from B. Kolb and I. Q. Whishaw, 2006, *An Introduction to Brain and Behavior*, 2d ed., Worth, p. 400; part (b) from Ed Reschke/Peter Arnold; parts (c) and (d) after N. Chaudhari and S. D. Roper, 2010, *J. Cell Biol.* **190**:285; part (e) after S. Frings, 2010, *PNAS* **107**:21955.]

Different bitter taste molecules are quite distinct in structure, which probably accounts for the need for the diverse family of T2Rs. Some T2R receptors bind only 2–4 bitter-tasting compounds, whereas others bind a wider variety of bitter compounds. The first member of the T2R family to be identified came from human genetics studies that showed an important bitterness-detection gene on chromosome 5. Mice that have five amino acid changes in the T2R protein T2R5 are unable to detect the bitter taste of cycloheximide (a protein synthesis inhibitor, see Table 9-1). Multiple T2R types

are often expressed in the same taste cell, and about 15 percent of all taste cells express T2Rs.

A dramatic gene regulation swap experiment was done to demonstrate the role of T2R proteins. Mice were engineered to express a bitter-taste receptor, a T2R protein, in cells that normally detect sweet tastants that attract mice. The mice developed a strong attraction for bitter tastes, evidently because the cells continued to send a “go and eat this” signal even though they were detecting bitter tastants. This experiment demonstrates that the specificity of taste cells is

determined within the cells themselves, and that the signals they send are interpreted according to the neural connections made by that class of cells. This in turn implies a highly regulated system connecting the different classes of taste receptor cells to specific higher regions of the brain.

Sweet and Umami Tastes Sweet and umami tastants are detected by a GPCR family called the *T1Rs*, which are related to the *T2Rs*. The three mammalian *T1Rs* differ from one another in a small number of amino acids. The *T1Rs* have very large extracellular domains that comprise the taste-binding domain of the protein. In the taste-sensing glutamate receptor, the extracellular domain closes around glutamate in a way that is described as analogous to a Venus flytrap. Unlike most GPCRs, which generally function as monomers, *T1Rs* form homodimers and heterodimers, which is thought to increase the repertoire of molecules that can act as signals. However, the code of responses to different molecules is still under investigation. Mice lacking *T1R2* or *T1R3* fail to detect sugar; it is thought that the actual receptor is a heterodimer of the two. *T1R3* appears to be a receptor for both sweet tastes and umami, and that is because it detects sweets when combined with *T1R2* and umami when it combines with *T1R1*. Accordingly, taste cells express *T1R1* or *T1R2* but not both, as otherwise they would send an ambiguous message to the brain.

Interestingly, sweet-taste receptors are also found on the surface of certain endocrine cells in the gut; these cells also express *gustducin* and several other taste transduction proteins. The presence of glucose in the gut causes these cells to secrete the hormone glucagon-like peptide-1 (GLP-1), which in turn regulates appetite, and enhances insulin secretion and gut motility. Thus certain cells of the gut “taste” glucose through the same mechanisms used by taste cells of the tongue.

Salty Taste Salt is sensed by a member of a family of Na^+ channels called *ENaC channels* (Figure 22-25d). Indeed, knocking out a critical *ENaC* subunit in taste buds impaired salty-taste detection in mice. The influx of Na^+ through the channel depolarizes the taste cell, leading to neurotransmitter release. The role of *ENaC* channels as salt sensors is evolutionarily ancient; *ENaC* proteins also detect salt when expressed in insects. In *Drosophila*, taste sensors are located in multiple places including the legs, so when the fly steps on something tasty, the proboscis extends to explore it further.

Sour Taste Perception of sourness is due to the detection of H^+ ions. Many sour tastants are weak organic acids (e.g., acetic acid in vinegar), which in their protonated forms diffuse through the plasma membrane. They then dissociate into an anion and a proton, which acidifies the cytosol. Strong acids like HCl are detected by a proton channel in the apical membrane of the sour-sensing cells that enables protons to reach the cytosol. Regardless of how the intracellular H^+ concentration is increased, protons are believed to block

an as-yet-unidentified proton-sensitive K^+ channel and thus depolarize the membrane (Figure 22-25e). As with salt detection, voltage-gated Ca^{2+} channels would then open, elevate cytosolic Ca^{2+} , and thus trigger exocytosis of neurotransmitter-filled synaptic vesicles.

A Plethora of Receptors Detect Odors

The perception of volatile airborne chemicals imposes different demands than the perception of light, sound, touch, or taste. Light is sensed by only four rhodopsin molecules, tuned to different wavelengths. Sound is detected by mechanical effects through hairs that are tuned to different wavelengths. Touch and pain requires a small number of different gated ion channels. The sense of taste measures a small number of substances dissolved in water. In contrast to all these other senses, olfactory systems can discriminate between many hundreds of volatile molecules moving through air. Discrimination between a large number of chemicals is useful in finding food or a mate, sensing pheromones, and avoiding predators, toxins, and fires. *Olfactory receptors* work with enormous sensitivity. Male moths, for example, can detect single molecules of the signals sent drifting through the air by females. In order to cope with so many signals, the olfactory system employs a large family of olfactory receptor proteins. Humans have about 700 olfactory receptor genes, of which about half are functional (the rest are unproductive pseudogenes), a remarkably large proportion of the estimated 20,000 human genes. Mice are more efficient, with more than 1200 olfactory receptor genes, of which about 800 are functional. That means 3 percent of the mouse genome is composed of olfactory receptor genes. *Drosophila* has about 60 olfactory receptor genes. In this section we will examine how olfactory receptor genes are employed, and how the brain can recognize which odor has been sensed—the initial stages of interpretation of our chemical world. Odor molecules are called *odorants*. They have diverse chemical structures, so olfactory receptors face some of the same challenges faced by antibodies and hormone receptors—the need to bind and distinguish many variants of relatively small molecules.

Olfactory receptors are seven-transmembrane-domain proteins (Figure 22-26). In mammals, olfactory receptors are produced by cells of the nasal epithelium. These cells, called *olfactory receptor neurons* (ORNs), transduce the chemical signal into action potentials. Each ORN extends a single dendrite to the luminal surface of the epithelium, from which immotile cilia extend to bind inhaled odorants from the air (Figure 22-27a). These olfactory sensory cilia are enriched in the odorant receptors and signal transduction proteins that mediate the initial transduction events. In *Drosophila*, ORNs have similar structures and are located in the antennae (Figure 22-27b).

In both mammals and *Drosophila* the ORNs project their axons to the next higher level of the nervous system, which in mammals is located in the olfactory bulb of the brain. The ORN axons synapse with dendrites from *mitral neurons* in mammals (called *projection neurons* in insects);

FIGURE 22-26 Signal transduction from the olfactory GPCRs.

Binding of an odorant to its cognate odorant receptor (OR) triggers activation of the trimeric G protein G_{olf} . $G_{\beta\gamma}$ releasing the active $G_{\alpha_{olf}} \cdot GTP$. Activated $G_{\alpha_{olf}} \cdot GTP$ in turn activates type III adenylyl cyclase (AC3), leading to the production of cyclic AMP (cAMP) from ATP. Molecules of cAMP bind to and open the cyclic nucleotide-gated (CNG) ion channel, leading to the influx of Na^+ and Ca^{2+} and depolarizing the cell. cAMP also activates protein kinase A (PKA), which phosphorylates and thus regulates transcription factors and other intracellular proteins.

these synapses occur in the clusters of synaptic structures called *glomeruli*. The mitral neurons connect to higher olfactory centers in the brain (Figure 22-28).

 Humans vary markedly in their ability to detect certain odors. Some cannot detect the steroid androstene, a compound derived from testosterone and found in human sweat. Some describe the odor as pleasant and musky, while others compare it to the smell of dirty socks. These differences are all ascribed to inactivating missense mutations in the gene encoding the single androstene GPCR. Individuals with two copies of the wild-type allele perceive androstene as unpleasant, whereas those possessing one or no functional alleles perceive androstene as less unpleasant or undetectable. ■

Despite the vast number of olfactory receptors, all generate the same intracellular signals through activation of the same trimeric G protein: $G_{olf} \cdot G_{\beta\gamma}$ (see Figure 22-26). G_{olf} is expressed mainly in olfactory neurons. Like G_{α_s} , the active $G_{\alpha_{olf}} \cdot GTP$ formed after ligand binding activates an adenylyl cyclase that leads to the production of cyclic AMP (cAMP; see Figure 15-27). Two downstream signaling pathways are activated by cAMP. It binds to a site on the cytosolic face of a cyclic nucleotide-gated (CNG) Na^+/Ca^{2+} channel, opening the channel and leading to an influx of Na^+ and Ca^{2+} and local depolarization of the cell membrane. This odorant-induced depolarization in the olfactory dendrites spreads

FIGURE 22-27 Structures of olfactory receptor neurons. Across a vast span of evolutionary distance—vertebrate and insect—olfactory receptor neurons have similar forms. (a) Vertebrate olfactory receptor neurons have one dendrite, which ends in a dendritic knob; from each dendritic knob, approximately 15 cilia extend into the nasal mucus. (b) Insect olfactory receptor neurons are morphologically similar: the bipolar neuron gives rise to a single basal axon that projects to an olfactory glomerulus in the antennal lobe. At its apical side it has a single dendritic process, from which sensory cilia extend. [Adapted from U. B. Kaupp, 2010, *Nature Rev. Neurosci.* 11:188–200.]

throughout the neuronal membrane, resulting in opening of voltage-gated Na^+ channels in the axon hillock and the generation of action potentials. Molecules of cAMP also activate protein kinase A (PKA), which phosphorylates and thus regulates transcription factors and other intracellular proteins.

Each Olfactory Receptor Neuron Expresses a Single Type of Odorant Receptor

The key to understanding the specificity of the olfactory system is that in both mammals and insects each ORN produces only a single type of odorant receptor. Any electrical signal from that cell will convey to the brain a simple message: “my odorant is binding to my receptors.” Receptors are not always completely monospecific for odorants. Some receptors can bind more than one kind of molecule, but the molecules detected are usually closely related in structure. Conversely, some odorants bind to multiple receptors.

There are about 5 million ORNs in the mouse, so on average each of the 800 or so olfactory receptor genes is active in approximately 6000 cells. There are about 2000 glomeruli (roughly 2 for each odorant receptor gene), so on average the axons from a few thousand ORNs converge on each glomerulus (see Figure 22-28). From there about 25 mitral axons per glomerulus, or a total of 50,000 mitral neurons, connect to higher brain centers. Thus the initial odorant sensing information is carried directly to higher parts of the brain without processing, a simple report of what odorant has been detected.

FIGURE 22-28 The anatomy of olfaction in the mouse.

(a) Schematic representation of a sagittal section through an adult mouse head. Axons of the olfactory receptor neurons (ORNs) in the main olfactory epithelium bundle to form the olfactory nerve and innervate the olfactory bulb. Each ORN of the main olfactory epithelium expresses only one odorant receptor gene. The vomeronasal organ and the accessory olfactory bulb are involved in pheromone sensing. (b) All of the olfactory receptor neurons that express a single type of receptor send their axons to the same glomerulus. In this figure each color represents the neural connections for each distinct expressed receptor. The glomeruli are located in the olfactory bulb near the brain; in the glomeruli, the ORNs synapse with *mitral neurons*; each mitral neuron has its dendrites localized to a single glomerulus and its corresponding ORNs, thus carrying information about a particular odorant to higher centers of the brain. Each glomerulus thus receives innervation from sensory neurons expressing a single odorant receptor, providing the anatomical basis of the olfactory sensory map. [After T. Komiyama and I. Luo, 2005, *Curr. Opin. Neurobiol.* 16:67–73 and S. Demaria and J. Ngai, 2010, *J. Cell Biol.* 191:443.]

The one neuron–one receptor rule extends to *Drosophila*. Detailed studies have been done in larvae, where a simple olfactory system with only 21 ORNs uses about 10–20 olfactory receptor genes. It appears that a unique receptor is expressed in each ORN, which sends its projections to one glomerulus. ORNs can send either excitatory or inhibitory signals from their axon termini, probably in order to distinguish attractive versus repulsive odors. Similar to mammals, the axons from the ORNs end in the glomeruli, which in flies are located in the antennal lobe of the larval brain. The research in *Drosophila* began with tests of which odorants bind to which receptors (Figure 22-29a). Some odorants are detected by a single receptor, some by several, so the combinatorial pattern allows many more odorants to be distinguished than just the number of different olfactory receptors. The small total number of neurons has allowed a map to be constructed showing which odorants are detected by every glomerulus (Figure 22-29b). One striking finding was that glomeruli located near each other respond to odorants with related chemical structures, e.g., linear aliphatic compounds or aromatic compounds. The arrangement may reflect evolution of new receptors concomitant with a process of subdivision of the olfactory part of the brain.

The simple system of having each cell make only one receptor type also has some impressive difficulties to overcome: (1) Each receptor must be able to distinguish a type of odorant molecule or a set of molecules with specificity adequate to the needs of the organism. A receptor stimulated too frequently would probably not be very useful. (2) Each cell must express one and only one receptor gene product. All the other receptor genes must be turned off. At the same time, the collective efforts of all the cells in the nasal epithelium must allow the production of enough different receptors to give the animal adequate sensory versatility. It does little good to have genes for hundreds of receptors if most of them are never expressed, but it is a regulatory challenge to turn on one and only one gene in each cell and at the same time express all the receptor genes across the complete popu-

lation of cells. (3) The neuronal wiring of the olfactory system must make discrimination among odorants possible so that the brain can determine which odorants are present. Otherwise the animal might be feeling at ease and relaxed when it should be running away as fast as possible.

The solution to the first problem is the great variability of the olfactory receptor proteins, both within and between species. The solution to the second problem, the expression of a single olfactory receptor gene per cell, has been explored using transgenic mice, but the mechanism is still not understood. When an engineered olfactory receptor gene is used to produce an olfactory receptor, other genes encoding receptor proteins are turned off transcriptionally, owing to some type of feedback regulation. If an engineered olfactory receptor gene is expressed that produces a reporter protein—not an olfactory receptor protein—then other genes can still be expressed. Thus the feedback system must involve detection of the presence of a functional olfactory receptor protein.

The third problem, how the system is wired so the brain can understand which odor has been detected, has been partly answered. First, ORNs that express the same receptor send their

EXPERIMENTAL FIGURE 22-29 Individual olfactory receptor types can be experimentally linked to various odorants and traced to specific glomeruli in the *Drosophila* larval olfactory system.

(a) The different olfactory receptor proteins are listed across the top, and the 27 odorants tested are shown down the left side. Colored dots indicate strong odor responses. Note that some odorants stimulate multiple receptors (e.g., pentyl acetate), while others (e.g., ethyl butyrate) act on only a single receptor. Note that many receptors, such as Or42a or Or67b, respond primarily to aliphatic compounds, whereas others, such as Or30a and Or59a, respond to aromatic compounds. (b) Spatial map of olfactory information in glomeruli of the *Drosophila* larval brain. The mapping was done by expressing a reporter gene under the control of each of the selected olfactory receptor neurons. The photograph indicates the glomeruli that receive projections from ORNs producing each of the ten indicated receptor protein types (Or42a, etc.). Also indicated are the odorants to which each receptor responds strongly. Note that with one exception (Or30a and Or45b) each glomerulus has unique sensory capacities. The exception might not be an exception if more olfactory gene expression patterns were tested. Glomeruli sensing odorants that are chemically similar tend to be situated next to one another. For example, the three glomeruli indicated by a blue solid line sense linear aliphatic compounds; those with yellow dashed lines, aromatic compounds. [Part (a) from S. A. Kreher, J. Y. Kwon, and J. R. Carlson, 2005, *Neuron* 46:445–456. Part (b) courtesy of Jae Young Kwon, Scott Kreher, and John Carlson.]

axons to the same glomerulus. Thus all cells that respond to the same odorant send processes to the same destination. In mice, a crucial clue about the patterning of the olfactory system came from the discovery that olfactory receptors play two roles in ORNs: odorant binding and, during development, axon guidance. Multiple ORN axons expressing the same receptor are

guided to the same glomerulus destination. The full mechanism is not known, but it is clear that ORN axons respond both to their own olfactory receptor and to standard axon-guidance molecules used in other parts of the nervous system.

KEY CONCEPTS of Section 23.4

Sensing the Environment: Touch, Pain, Taste, and Smell

- Mechanoreceptors and pain receptors are gated Na^+ or $\text{Na}^+/\text{Ca}^{2+}$ channels.
- Touch sensitivity requires several cytoskeletal and extracellular matrix proteins as well as a gated Na^+ channel (see Figure 22-24).
- Five primary tastes are sensed by subsets of cells in each taste bud. Salty and sour tastes are detected by specific channel proteins, and G protein-coupled receptors detect sweetness, umami, and bitterness.
- In all cases, tastants lead to membrane depolarization and secretion of small molecules such as ATP that stimulate the adjacent neurons. Some tastant GPCRs are found in different homo- and heterodimeric combinations to detect different tastes (see Figure 22-25).
- Odorant receptors, which are seven-transmembrane G protein-coupled receptors, are encoded by a very large set of genes. Any one olfactory receptor neuron expresses one and only one olfactory receptor gene, so a signal from that cell to the brain unambiguously conveys the nature of the chemical sensed.

- ORNs that express the same receptor gene send their axons to the same glomerulus, and projection nerves (mitral neurons in mammals) carry odorant-specific information from the glomeruli to the brain (see Figures 22-27, 22-28, and 22-29).

Perspectives for the Future

In this chapter we have provided an introduction to the remarkable properties of the nerve cells that serve as our interface with the world. The human body contains multiple types of neurons, each with its own shape, neurotransmitter, number of dendrites, length of axon, and numbers of connections with other neurons. How each of these types of cells develops in precisely the right place and makes appropriate synaptic connections with other neurons and appropriate contacts with surrounding glia remains largely a mystery. What, for instance, are the extracellular signals, transcriptional regulatory circuits, and induced or repressed proteins that tell a neuron to become myelinated or to generate a specific number of dendrites of a specific length? How does a neuron achieve its very long, polarized, branching structure? Why does one part of a neuron become a dendrite and another an axon? Why are certain key membrane proteins clustered at particular points—neurotransmitter receptors in postsynaptic densities in dendrites, Ca^{2+} channels in axon termini, and Na^+ channels in myelinated neurons at the nodes of Ranvier? Such questions of cell shape and protein targeting also apply to other types of cells, but the morphological diversity of different types of neurons makes these particularly intriguing questions in the nervous system.

A detailed understanding of the structure and function of nerve cells will require knowledge of the three-dimensional structures of many different channels, neurotransmitter receptors, other membrane proteins, and cytoskeletal proteins. While the determination of the structure of the first voltage-gated K^+ channel has illuminated the mechanisms of channel gating that likely apply to other voltage-gated channels, we lack structures for any calcium channels. We do not know the structures for any of the “pain receptors” and thus we cannot rationally derive structures of putative antagonists that might be useful in pain control. We know the structures of only a few of the hundreds of G protein-coupled receptors used in the nervous system—none in the olfactory system—and thus the details of how these receptors differentiate between closely related ligands remain obscure.

From the standpoint of molecular cell biology, some of the greatest excitement has surrounded research into mechanisms of memory. In most cases memory does not depend on forming new neurons. Instead, existing neurons are modified; changes in the number and strength of synapses often underlie the establishment and endurance of memories. Current studies are directed at the molecular changes that alter synapses, both in the pre- and postsynaptic cells. For exam-

ple, in many neurons in the mammalian brain the dendritic spines that emerge from dendrites and form synapses with other neurons are constantly forming and disappearing depending on the degree of stimulation of the nerve by other neurons. Such changes affect the ability of the postsynaptic neuron to respond to signals from presynaptic ones; the idea that it might relate to functional plasticity of synapses needs to be tested further.

The advances in the cell biology of the nervous system have been paralleled by extraordinary advances in exploring how neural circuitry carries out the interpretation of sensory information, analytical thought, feedback mechanisms for motor control, establishment and retrieval of memories, inheritance of instincts, regulated hormonal control, and emotional responses. Some experiments are done with noninvasive imaging technologies, observing thousands to millions of neurons and detecting global electrical activity. Others are done by observing *in vivo* a few cells at a time using inserted electrodes. This is being accomplished by improvements in imaging methods (invasive and noninvasive) combined with the development of better ways to manipulate the activities of single neurons, or of large numbers of neurons simultaneously. For instance, one can generate transgenic mice that express in specific sets of neurons an engineered Na^+ channel protein that is activated by light; a focused microscopic light beam will excite these cells but no others, and one can observe the consequences for the behavior of the animal. There is every reason to expect these advances to continue, an exciting prospect for understanding the brain and doing a better job of treating diseases that affect the nervous system.

Key Terms

action potential 1021	neuromuscular
Agrin 1037	junction 1037
astrocytes 1023	neuron 1020
axon 1021	neurotransmitters 1022
dendrites 1021	nociceptors 1048
depolarization 1021	node of Ranvier 1033
endocytosis 1037	odorants 1050
excitatory receptor 1045	olfactory receptors 1050
glial cells 1023	oligodendrocytes 1023
glomeruli 1051	refractory period 1027
hyperpolarization 1027	repolarization 1021
inhibitory receptor 1045	saltatory conduction 1033
interneuron 1020	Schwann cells 1023
ligand-gated channel 1043	sensory neuron 1020
motor neuron 1020	synapse 1022
MuSK 1037	synaptic vesicles 1022
myelin sheath 1021	voltage-gated channel 1025

Review the Concepts

1. What is the role of glial cells in the brain and other parts of the nervous system?
2. The resting potential of a neuron is -60 mV inside compared with outside the cell. How is the resting potential maintained in animal cells?
3. Name the three phases of an action potential. Describe for each the underlying molecular basis and the ion involved. Why is the term *voltage-gated channel* applied to Na^+ channels involved in the generation of an action potential?
4. Explain how the crystal structures of potassium ion channels suggest the way in which the voltage-sensing domains interact with other parts of the proteins to open and close the ion channels. How does this structure-function relationship apply to other voltage-gated ion channels?
5. Explain why the strength of an action potential doesn't decrease as it travels down an axon.
6. Explain why the membrane potential does not continue to increase, but rather, plateaus and then decreases during the course of an action potential.
7. What does it mean to say that action potentials are "all or none"?
8. What prevents a nerve signal from traveling "backwards" toward the cell body?
9. Why is the cell unable to initiate another action potential if stimulated during the refractory period?
10. Myelination increases the velocity of action potential propagation along an axon. What is myelination? Myelination causes clustering of voltage-gated Na^+ channels and Na^+/K^+ pumps at nodes of Ranvier along the axon. Predict the consequences to action potential propagation of increasing the spacing between nodes of Ranvier by a factor of 10.
11. Describe the mechanism of action for addictive drugs such as cocaine.
12. Acetylcholine is a common neurotransmitter released at the synapse. Predict the consequences for muscle activation of decreased acetylcholine esterase activity at nerve-muscle synapses.
13. Describe the ion dynamics of the muscle-contraction process.
14. Following the arrival of an action potential in stimulated cells, synaptic vesicles rapidly fuse with the presynaptic membrane. This happens in less than 1 ms. What mechanisms allow this process to take place at such great speed?
15. Neurons, particularly those in the brain, receive multiple excitatory and inhibitory signals. What is the name of the extension of the neuron at which such signals are received? How does the neuron integrate these signals to determine whether or not to generate an action potential?
16. Explain the mechanism by which action potentials are prevented from being propagated to a postsynaptic cell if transmitted across an inhibitory synapse.

17. What is the role of dynamin in recycling synaptic vesicles? What evidence supports this?

18. Compare and contrast electrical and chemical synapses.

19. Compare the structures and functions of the receptor molecules for salty and sour taste; the taste-receptor molecules for sweetness, bitterness, and umami; and odor-receptor molecules.

Analyze the Data

Olfaction occurs when volatile compounds bind to specific odorant receptors. In mammals, each olfactory receptor neuron in the olfactory nasal epithelium expresses a single type of odorant receptor. These odorant receptors constitute a large multigene family (>1000 members) of related proteins. Binding of odorant induces a signaling cascade that is mediated via a G protein, $G_{\alpha_{\text{olf}}}$. Recent studies suggest that there are a small number of olfactory sensory neurons in the nasal epithelium that express members of the trace-amine-associated receptor (TAAR) family, chemoreceptors that are G protein-coupled receptors (GPCRs) but are unrelated to classical odorant receptors (see Liberles and Buck, 2006, *Nature* 442:645–650). The mouse genome encodes 15 TAAR genes while the human genome encodes 6.

a. In order to examine the expression pattern of different TAARs in the olfactory nasal epithelium, researchers localized TAAR RNA by *in situ* hybridization in pairwise combinations. All possible pairwise combinations of the 15 mouse TAARs were examined. A typical example of the results obtained is shown in the top set of panels in the figure below, in which TAAR6 and TAAR7 have been localized with fluorescent probes in mouse nasal epithelium. The TAAR6 probe was labeled with a green fluor, the TAAR7 probe with a red fluor. The lower set of panels shows localization of mouse odorant receptor 28 (MOR28; green), a classical odorant receptor, and TAAR6 (red). Each stained patch in the images is the staining pattern of an individual olfactory neuron. The "merge" panels show the two other images superimposed. What do these data suggest about expression patterns of the TAARs?

b. A number of cell lines that produce neither classical odorant receptors nor TAARs have each been transfected with the

gene encoding a different TAAR. The cells have also been co-transfected with a gene encoding secreted alkaline phosphatase (SEAP) under control of a cAMP-responsive element. The cells were then exposed to various amines, as shown in the following figure, and SEAP activity in the medium was determined. The figure shows data for some representative TAARs (m = mouse, h = human). What do these data reveal about TAARs? What does the SEAP activity assay reveal about the signaling pathway utilized by chemoreception involving TAARs?

c. In a third set of studies, SEAP activity was measured in cells expressing mouse TAAR5 (mTAAR5) following exposure of the cells to diluted urine derived from two strains of mice or from humans, as indicated on the graphs in the next column. Mice reach puberty at about one month of age.

What do these data suggest may be a biological function for the TAAR5 neurons in mice? What additional studies would you conduct to support your hypothesis?

Immunology

Immunity is a state of protection against the harmful effects of exposure to pathogens. Host defense can take many different forms, and all successful pathogens have found ways to disarm the immune system or manipulate it to their own advantage. Host–pathogen interactions are therefore an evolutionary work in progress. This explains why we continue to be assaulted by pathogenic viruses, bacteria, and parasites. The prevalence of infectious diseases illustrates the imperfections of host defense. An immune system that could produce perfect sterilizing immunity would yield a world without pathogens, an outcome clearly at variance with life as we know it. Rather, the co-evolution of pathogens and their hosts allows pathogens, which have relatively short generation times, to continue to evolve sophisticated countermeasures, against which the host must respond by adjusting, if not improving, its defenses. Sophisticated defense comes at a price: an immune system capable of dealing with a massively diverse collection of rapidly evolving pathogens may mount an attack on the host organism's own cells and tissues, a phenomenon called *autoimmunity*.

In this chapter we deal mostly with the vertebrate immune system, with particular emphasis on those molecules, cell types, and pathways that uniquely distinguish the im-

mune system from other types of cell and tissues. Two remarkable features that characterize the vertebrate immune system are its ability to distinguish between closely related substances (**specificity**) and its ability to recall previously experienced exposure to a foreign substance (**memory**). This is accomplished through the generation of a massively diverse set of antigen-specific receptors (**diversity**), trained on self-molecules and largely purged of self-reactive components (**tolerance**), although clearly none of these desirable goals is accomplished with absolute precision.

From a practical perspective, the powers of the immune system are exploited not only therapeutically: monoclonal antibodies are a multibillion-dollar market in the successful treatment of inflammatory conditions, autoimmunity, and cancer. The molecules that comprise the adaptive immune system—antibodies in particular—are indispensable tools for the cell biologist. Antibodies allow the visualization and isolation of the molecules they recognize, and can do so with pinpoint precision. Their ability to do so has been invaluable in the accurate description of the components that make up the cell and its organelles, and their localization, both in cells and in tissues.

FIGURE 23-1 The three layers of vertebrate immune defenses.

Left: Mechanical defenses consist of epithelia and skin. Chemical defenses include the low pH of the gastric environment and antibacterial enzymes in tear fluid. These barriers provide continuous protection against invaders. Pathogens must physically breach these defenses (step **1**) to infect the host. *Middle:* Pathogens that have breached the mechanical and chemical defenses (step **2**) are handled by cells and molecules of the innate immune system (blue), which includes phagocytic cells (neutrophils, dendritic cells, macrophages), natural killer (NK) cells, complement proteins, and certain interleukins

(IL-1, IL-6). Innate defenses are activated within minutes to hours of infection. *Right:* Pathogens that are not cleared by the innate immune system are dealt with by the adaptive immune system (step **3**), in particular B and T lymphocytes. Full activation of adaptive immunity requires days. The products of an innate response may potentiate an ensuing adaptive response (step **4**). Likewise, the products of an adaptive immune response, including antibodies (Y-shaped icons), may enhance innate immunity (step **5**). Several cell types and secreted products straddle the fence between the innate and adaptive immune systems, and serve to connect these two layers of host defense.

Host defense comprises three layers: (1) mechanical/chemical defenses, (2) innate immunity, and (3) adaptive immunity (Figure 23-1). Mechanical and chemical defenses operate continuously. Innate immune responses, which involve cells and molecules present at all times, are rapidly activated (minutes to hours), but their ability to distinguish among many different pathogens is somewhat limited. In contrast, adaptive immune responses take several days to develop fully and are highly specific; that is, they can distinguish between closely related pathogens based on very small molecular differences in structure.

The manner in which **antigens**—any material that can evoke an immune response—are recognized and how these foreign materials are eliminated involves molecular and cell biological principles unique to the immune system. We begin this chapter with a brief sketch of the organization of the mammalian immune system, introducing the essential players of innate and adaptive immunity and describing inflammation, a local-

ized response to injury or infection that leads to the activation of immune-system cells and their recruitment to the affected site. In the next two sections, we discuss the structure and function of **antibody** (or immunoglobulin) molecules, which bind to specific molecular features on antigens, and how variability in antibody structure contributes to specific recognition of antigens. The enormous diversity of antigens that can be recognized by the immune system finds its explanation in unique rearrangements of the genetic material in B and T lymphocytes, commonly called **B cells** and **T cells**, which are the white blood cells that carry out antigen-specific recognition. These gene rearrangements not only control the specificity of antigen receptors on lymphocytes, they also determine cell-fate decisions in the course of lymphocyte development.

Although the mechanisms that give rise to antigen-specific receptors on B and T cells are very similar, the manner in which these receptors recognize antigens is very different.

The receptors on B cells can interact with intact antigens directly, but the receptors on T cells cannot. Instead, as described in Section 23.4, the receptors on T cells recognize processed (cleaved) forms of antigen, presented on the surface of target cells by glycoproteins encoded by the major histocompatibility complex (MHC). How MHC-encoded glycoproteins display these processed antigens is important for our understanding of how immune responses are initiated, not only to understand the physiology of the immune response but also for practical reasons. How can we best make antibodies that afford protection against an infectious agent? How can we raise antibodies as tools that recognize our favorite protein in a laboratory setting? Knowledge of antigen processing and presentation thus informs both vaccine design to protect against infectious disease and the generation of tools essential for research. MHC-encoded glycoproteins also help determine the developmental fate of T cells so that an organism's own cells and tissues (self antigens) normally do not evoke an immune response, whereas foreign antigens do. We conclude the chapter with an integrated view of the immune response to a pathogen, highlighting the collaboration between different immune-system cells that is required for an effective response.

23.1 Overview of Host Defenses

Because the immune system evolved to deal with pathogens, we begin our overview of host defenses by examining where typical pathogens are found and where they replicate. Then we introduce basic concepts of innate and adaptive immunity, including some of the key cellular and molecular players.

Pathogens Enter the Body Through Different Routes and Replicate at Different Sites

Exposure to pathogens occurs via different routes. The skin itself has a surface area of ≈ 20 sq. ft.; the epithelial surfaces that line the airways, gastrointestinal tract, and genital tract present an even more formidable surface area of ≈ 4000 sq. ft. All these surfaces are continuously exposed to viruses and bacteria in the environment. Food-borne pathogens and sexually transmitted agents target the epithelia to which they are exposed. The sneeze of a flu-infected individual releases millions of virus particles in aerosolized form, ready for inhalation by the next person to be infected. Rupture of the skin, even if only by minor abrasions, or of the epithelial barriers that protect the underlying tissues, provides an easy route of entry for pathogens, which then gain access to a rich source of nutrients (for bacteria) and to the cells required for their replication (viruses).

Replication of viruses is confined strictly to the cytoplasm or nucleus of host cells, where protein synthesis and replication of the viral genetic material occur. Viruses spread to other cells either as free virus particles (virions) or by cell-to-cell spread. Many bacteria can replicate in the intercellular space, but some are specialized to invade host cells and survive there. Such intracellular bacteria reside either in membrane-delimited vesicles

through which they enter cells by endocytosis or phagocytosis or in the cytoplasm if they escape from these vesicles. An effective host defense system, therefore, needs to be capable of eliminating not only cell-free viruses and free-living bacteria but also cells that harbor these pathogens.

Parasitic organisms can also cause disease. With increasingly complex life styles such as those of the protozoa that cause sleeping sickness (trypanosomes) or malaria (*Plasmodium* species), the pathogen's countermeasures also become increasingly complex. Bacteria, protozoa, and fungi—especially those that can cause disease in animals—often are called microbes.

Leukocytes Circulate Throughout the Body and Take Up Residence in Tissues and Lymph Nodes

With the exception of erythrocytes, few cells in the course of their assigned function cover such distances as do the cells that provide immunity. The mammalian circulation serves as the necessary transport vehicle for erythrocytes, leukocytes, and platelets. Although erythrocytes never leave the circulation (their oxygen-carrying function does not require it), leukocytes (white blood cells) use the circulation exclusively for transport. The transport function of the circulation ensures delivery of lymphocytes from the sites where they are generated (bone marrow, thymus, fetal liver) to the sites where they can be activated (lymph nodes, spleen), and then to the site of infection, where they can eradicate invaders. Once lymphocytes arrive at a given location, they may leave and re-enter the circulation in the course of their tasks.

The immune system is an interconnected system of vessels, organs, and cells, divided into primary and secondary lymphoid structures (Figure 23-2). *Primary lymphoid organs*—the sites at which lymphocytes (the subset of leukocytes that includes B and T cells) are generated and acquire their functional properties—include the thymus, where T cells are generated, and the bone marrow, where B cells are generated. Adaptive immune responses, which require functionally competent lymphocytes, are initiated in *secondary lymphoid organs* including lymph nodes and the spleen. All of the lymphoid organs are populated by cells of hematopoietic origin (see Figure 21-18), generated in the fetal liver and throughout life in the bone marrow. The total number of lymphocytes in a young adult male is estimated to be 500×10^9 , roughly 15 percent of which are found in the spleen, 40 percent in the other secondary lymphoid organs (tonsils, lymph nodes), 10 percent in the thymus, and 10 percent in the bone marrow; the remainder are circulating in the bloodstream.

Vertebrate blood vessels allow the escape of fluid from the circulation, driven by the positive arterial pressure exerted by the pumping heart. This fluid contains not only nutrients but also proteins that carry out defensive functions. To maintain homeostasis, the fluid that leaves the circulation must ultimately return and does so in the form of *lymph*, via lymphatic vessels. The total volume of lymph is up to three times the total blood volume. At their most distal ends, lymphatic vessels are open to collect the interstitial fluid that bathes the cells in tissues. The lymphatic vessels merge into larger collecting

FIGURE 23-2 The Circulatory and Lymphatic Systems. Positive arterial pressure exerted by the pumping heart is responsible for loss of liquid from the circulation (red) into the interstitial spaces of the tissues, so that all cells of the body have access to nutrients and can dispose of waste. This interstitial fluid, whose volume is roughly three times that of all blood in the circulation, is returned to the circulation in the form of lymph, which passes through specialized anatomical structures called lymph nodes. The primary lymphoid organs, where lymphocytes are generated, are the bone marrow (B cells, T-cell precursors) and the thymus (T cells). The initiation of an immune response involves the secondary lymphoid organs (lymph nodes, spleen).

vessels, which deliver lymph to *lymph nodes*. A lymph node consists of a capsule, organized into areas that are defined by the cell types that inhabit them. Blood vessels entering a lymph node deliver B and T cells to it. The lymph that arrives in a lymph node carries cells that have encountered (“sampled”) antigen, as well as soluble antigens, from the tissue drained by that particular afferent lymphatic vessel. In the lymph node, the cells and molecules required for the adaptive immune response interact, respond to the newly acquired antigenic information, and then execute the necessary effector functions to rid the body of the pathogen (Figure 23-3).

Lymph nodes can be thought of as filters in which antigenic information gathered from distal sites throughout the body is collected and displayed to the immune system in a form suitable to evoke an appropriate response. All the rele-

vant steps that lead to lymphocyte activation take place in lymphoid organs. Cells that have received proper instructions to become functionally active leave the lymph node via efferent lymphatic vessels that ultimately drain into the circulation. Such activated cells recirculate through the bloodstream and—now ready for action—may reach a location where they again leave the circulation, move into tissues, and seek out pathogenic invaders or destroy virus-infected cells.

The exit of lymphocytes and other leukocytes from the circulation, recruitment of these cells to sites of infection, processing of antigenic information, and return of immune-system cells to the circulation are all carefully regulated processes that involve specific cell-adhesion events, chemotactic cues, and the traversal of endothelial barriers, as we discuss later.

Mechanical and Chemical Boundaries Form a First Layer of Defense Against Pathogens

As noted already, mechanical and chemical defenses form the first line of host defense against pathogens (see Figure 23-1). Mechanical defenses include the skin, epithelia, and arthropod exoskeleton, which are barriers that can be breached only by mechanical damage or through specific chemo-enzymatic attack. Chemical defenses include not only the low pH found in gastric secretions but also enzymes such as *lysozyme*, found in tear fluid, which can attack microbes directly.

The importance of mechanical defenses, which operate continuously, are immediately obvious in the case of burn victims. When the integrity of the epidermis and dermis is compromised, the rich source of nutrients in the underlying tissues is exposed, and airborne bacteria or otherwise harmless bacteria found on the skin can multiply unchecked, ultimately overwhelming the host. Viruses and bacteria have also evolved strategies to breach the integrity of these physical barriers. Enveloped viruses such as HIV, rabies virus, and influenza virus possess membrane proteins endowed with fusogenic properties. Following adhesion of a virion to the surface of the cell to be infected, direct fusion of the viral envelope with the host cell’s membrane results in delivery of the viral genetic material into the host cytoplasm, where it is now available for transcription, translation, and replication (see Figures 4-47 and 4-49). Certain pathogenic bacteria (e.g., *S. aureus*) secrete collagenases that compromise the integrity of connective tissue and so facilitate entry of the bacteria.

Innate Immunity Provides a Second Line of Defense After Mechanical and Chemical Barriers Are Crossed

The innate immune system is activated once the mechanical and chemical defenses have failed, and the presence of an invader is sensed (see Figure 23-1). The innate immune system comprises cells and molecules that are immediately available for responding to pathogens. **Phagocytes**, cells that ingest and destroy pathogens, are widespread throughout tissues and epithelia and can be recruited to sites of infection. Several soluble proteins present constitutively in the blood, or produced in response to infection or inflammation,

FIGURE 23-3 Initiation of the adaptive immune response in lymph nodes. Recognition of antigen by B and T cells (lymphocytes) located in lymph nodes initiates an adaptive immune response. Lymphocytes leave the circulation and take up residence in lymph nodes (step 1). Lymph carries antigen in two forms—soluble antigen and antigen-laden dendritic cells; both are delivered to lymph nodes via afferent lymphatics (steps 2, 3). Soluble antigen is recognized by

B cells (step 4), and antigen-laden dendritic cells present antigen to T cells (step 5). Productive interactions between T and B cells (step 6) allow B cells to move into follicles and differentiate into plasma cells, which produce large amounts of secreted immunoglobulins (antibodies). Efferent lymphatic vessels return lymph from the lymph node to the circulation.

also contribute to innate defense. Animals that lack an adaptive immune system, such as insects, rely exclusively on innate defenses to combat infections.

Phagocytes and Antigen-Presenting Cells The innate immune system includes macrophages, neutrophils, and dendritic cells. All of these cells are phagocytic and come equipped with **Toll-like receptors (TLRs)**. Members of this family of cell-surface proteins detect broad patterns of pathogen-specific markers and thus are key sensors for detecting the presence of viral or bacterial invaders. Engagement of Toll-like receptors is important in eliciting effector molecules, including antimicrobial peptides. **Dendritic cells** and **macrophages** whose Toll-like receptors have detected pathogens also function as **antigen-presenting cells (APCs)** by displaying processed foreign materials to antigen-specific T cells. The structure and function of Toll-like receptors and their role in activating dendritic cells are described in detail in Section 23.6.

Complement System Another important component of the innate immune system is **complement**, a collection of serum

proteins that can bind directly to microbial or fungal surfaces. This binding activates a proteolytic cascade that culminates in, among other things, formation of pore-forming proteins constituting the **membrane attack complex**, which is capable of permeabilizing the pathogen's protective membrane (Figure 23-4). The complement cascade is conceptually similar to the blood-clotting cascade, with amplification of the reaction at each successive stage of activation. At least three distinct pathways can activate complement. The **classical pathway** requires the presence of antibodies produced in the course of an adaptive response and bound to the surface of the microbe. How such antibodies are produced will be described below. Many microbial surfaces have physico-chemical properties, incompletely understood, that result in activation of complement via the **alternative pathway**. Finally, pathogens that contain mannose-rich cell walls activate complement through the **mannose-binding lectin pathway**. The bound lectin then triggers activation of two mannose-binding lectin-associated proteases, **MASP-1** and **MASP-2**, which allow activation of the downstream components of the complement cascade. The three pathways converge at the activation of complement protein **C3**.

FIGURE 23-4 Three pathways of complement activation.

The classical pathway involves the formation of antibody-antigen complexes, while in the mannose-binding lectin pathway, mannose-rich structures found on the surface of many pathogens are recognized by mannose-binding lectin. The alternative pathway requires deposition of a special form of the serum protein C3, a major complement component, onto a microbial surface. Each of the activation pathways is organized as a cascade of proteases in which the downstream component is itself a protease. Amplification of activity occurs with each successive step. All three pathways converge on C3, which cleaves C5 and thus triggers formation of the membrane attack complex, leading to destruction of target cells. The small fragments of C3 and C5 generated in the course of complement activation initiate inflammation by attracting neutrophils, phagocytic cells that can kill bacteria at short range or upon ingestion.

C3 is synthesized as a precursor that contains an internal, strained thioester linkage between a cysteine and a glutamate residue in close proximity. This thioester linkage becomes highly reactive upon proteolytic activation of C3. The activated thioester bond in C3 can react with primary amines or hydroxyls in close proximity, yielding a covalent bond linking C3 with a nearby protein or carbohydrate. If no such reactants are available, the thioester bond is simply hydrolyzed and renders the hydrolysis product inactive. This mode of action ensures that C3 will be covalently deposited only on antigen-antibody complexes in close proximity. Surfaces properly decorated with mannose-binding lectin or that received C3 deposits via the alternative pathway are similarly targeted. This limits the effects of complement to nearby surfaces, avoiding an inappropriate attack on cells that do not display the antigens targeted.

Regardless of the activation pathway, activated C3 unleashes the terminal components of the complement cascade, C5 through C9, culminating in formation of the membrane attack complex, which inserts itself into most biological membranes and renders them permeable. The resulting loss of electrolytes and small solutes leads to lysis and death of the target cell. Whenever complement is activated, the membrane attack complex is formed and results in death of the cell onto which this complex is deposited. The direct microbicidal effect of a fully activated complement cascade is an important protective function.

All three complement activation pathways also generate the C3a and C5a cleavage fragments, which bind to G protein-coupled receptors and function as chemoattractants for neutrophils and other cells involved in inflammation (see below). All three pathways also result in the covalent decoration of the structures targeted by complement activation with fragments of C3. Phagocytic cells make use of these C3-derived tags to recognize, ingest, and destroy the decorated particles, a process termed *opsonization*.

The complement cascade thus fulfills multiple roles in host defense: it can destroy the membranes that envelope a pathogen (bacteria, viruses); it covalently “paints” the targeted pathogen so that it may be more readily ingested by phagocytic cells capable of killing the pathogen and present-

ing its contents to cells that will initiate an adaptive immune response; and finally, the act of complement activation yields chemotactic signals to attract cells of the innate (neutrophils, macrophages, dendritic cells) and adaptive (lymphocytes) immune system to the site of infection.

Natural Killer (NK) Cells In addition to bacterial invaders, the innate immune system also defends against viruses. When the presence of a virus-infected cell is detected, yet other cell types of the innate immune system become active, seek out the virus-infected targets, and kill them. For instance, many virus-infected cells produce type I **interferons**, which are good at activating **natural killer (NK) cells**. Activated NK cells not only afford direct protection by eliminating the factory of new virus particles, they also secrete interferon γ

FIGURE 23-5 Natural killer cells. Natural killer (NK) cells are an important source of the cytokine interferon γ (IFN- γ) and can kill virus-infected and cancerous cells by means of perforins. These pore-forming proteins allow access of serine proteases called granzymes to the cytoplasm of the cell about to be killed. Granzymes also can initiate apoptosis through activation of caspases (Chapter 21). NK receptors identify infected or stressed cells and stimulate the NK cell to kill them. Other receptors identify normal cells and inhibit NK cell activation.

(IFN- γ), which is essential for orchestrating many aspects of antiviral defenses (Figure 23-5). Recognition by NK cells involves several classes of receptor, capable of delivering either stimulatory (promoting cell killing) or inhibitory signals. The interferons are classified as **cytokines**, small, secreted proteins that help regulate immune responses in a variety of ways. We will encounter other cytokines and discuss some of their receptors as the chapter progresses.

Inflammation Is a Complex Response to Injury That Encompasses Both Innate and Adaptive Immunity

When a vascularized tissue is injured, the stereotypical response that follows is **inflammation**. Damage may be a simple paper cut or result from infection with a pathogen. Inflammation, or the inflammatory response, is characterized by four classical signs: *redness*, *swelling*, *heat*, and *pain*. These signs are caused by increased leakiness of blood vessels (vasodilation), the attraction of cells to the site of damage, and the production of soluble mediators responsible for the sensation of heat and pain. Inflammation has immediate protective value through the activation of the cell types and soluble products that together mount the innate immune response. Further, inflammation creates a local environment conducive to the initiation of the adaptive immune response. However, if it is not properly controlled, inflammation can also be a major cause of tissue damage.

Figure 23-6 depicts the key players in the inflammatory response to bacterial pathogens and the subsequent initiation

FIGURE 23-6 Interplay of innate and adaptive immune responses against a bacterial pathogen. Once a bacterium breaches the host's mechanical and chemical defenses, the bacterium is exposed to components of the complement cascade, as well as to cells that confer immediate protection, such as neutrophils (step 1). Various inflammatory mediators induced by tissue damage contribute to a localized inflammatory response. Local destruction of the bacterium results in the release of bacterial antigens, which are delivered via the afferent lymphatics to the draining lymph node (step 2). Dendritic cells acquire antigen at the site of infection, become migratory in response to microbial products, and move to the lymph node, where they activate T cells (step 3). In the lymph node, antigen-stimulated T cells proliferate and acquire effector functions, including the ability to help B cells (step 4), some of which may move to the bone marrow and complete their differentiation into plasma cells there (step 5). In later stages of the immune response, activated T cells provide additional assistance to antigen-experienced B cells to yield plasma cells that secrete antigen-specific antibodies at a high rate (step 6). Antibodies produced as a consequence of the initial exposure to bacteria act in synergy with complement to eliminate the infection (step 7), should it persist, or afford rapid protection in the case of re-exposure to the same pathogen.

of an adaptive immune response. Tissue-resident dendritic cells sense the presence of pathogens via their Toll-like receptors (TLRs) and respond to them by releasing soluble mediators such as cytokines and **chemokines**; the latter act as chemoattractants for immune-system cells. **Neutrophils**, a second important cell type in the inflammatory response, leave the circulation and migrate to wherever tissue injury or infection has occurred in response to cytokines and chemokines produced upon tissue damage. Neutrophils, which constitute almost half of all circulating leukocytes, are phagocytic, directly ingesting and destroying pathogenic bacteria and fungi. Neutrophils can interact with a wide variety of pathogen-derived macromolecules via their Toll-like receptors. Activation of these receptors allows neutrophils to produce cytokines and chemokines; the latter can attract more leukocytes—neutrophils, macrophages, and ultimately lymphocytes (T and B cells)—to the area. Activated neutrophils can release bacteria-destroying enzymes (e.g., lysozyme and proteases) as well as small peptides with microbicidal activity, collectively called *defensins*. Activated neutrophils also turn on the enzymes that generate superoxide anion and other reactive oxygen species (see Chapter 12, p. 541), which can kill microbes at short range. Another cell type contributing to the inflammatory response is tissue-resident *mast cells*. When activated by a variety of physical or chemical stimuli, mast cells release histamine, a mediator that increases vascular permeability and thereby facilitates access to plasma proteins (e.g., complement) that can act against the invading pathogen.

A very important early response to infection or injury is activation of a variety of plasma proteases, including the proteins of the complement cascade discussed above (see Figure 23-4). The peptides produced during activation of these proteases possess chemoattractant activity, responsible for attracting neutrophils to the site of tissue damage. They further induce production of proinflammatory cytokines such as interleukin 1 and 6 (IL-1 and IL-6). The recruitment of neutrophils also depends on an increase in vascular permeability, controlled in part by lipid mediators (e.g., prostaglandins and leukotrienes) that are derived from phospholipids and fatty acids. All of these events occur rapidly, starting within minutes of injury. A failure to resolve the cause of this immediate response may result in chronic inflammation, in which cells of the adaptive immune system play an important role.

When the pathogen burden at the site of tissue damage is high, it may exceed the capacity of innate defense mechanisms to deal with them. Moreover, some pathogens have acquired, in the course of evolution, tools to disable or bypass innate immune defenses. In such situations, the adaptive immune response is required to control the infection. This adaptive response depends on specialized cells that straddle the interface between adaptive and innate immunity, including antigen-presenting cells such as macrophages and dendritic cells, which are capable of acquiring intact pathogens and of killing them upon ingestion. These antigen-presenting cells, in particular, dendritic cells, can initiate an adaptive immune response by delivering newly acquired pathogen-derived antigens to secondary lymphoid organs (see Figure 23-6).

Adaptive Immunity, the Third Line of Defense, Exhibits Specificity

Adaptive immunity is the term reserved for the highly specific recognition of foreign substances, the full elaboration of which requires days or weeks after occurrence of the initial exposure to evolve. Lymphocytes bearing antigen-specific receptors are the key cells responsible for adaptive immunity. An early indication of the specific nature of adaptive responses came with the discovery of **antibodies**, key effector molecules of adaptive immunity, by Emil von Behring and Shibasaburo Kitasato in 1905. They began by transferring serum (the straw-colored liquid that separates from cellular debris upon completion of the blood-clotting process) from guinea pigs immunized with a sublethal dose of the deadly diphtheria toxin to animals never before exposed to the bacterium. The recipient animals were thus protected against a lethal dose of the same bacterium (Figure 23-7, *left*). Transfer of serum from animals never exposed to diphtheria toxin failed to protect, and protection was limited to the microbe that produced the diphtheria toxin. This experiment demonstrates *specificity*—that is, the ability to distinguish between two related substances, toxins, of the same class. Such specificity is a hallmark of the adaptive immune system. Even proteins that differ by a single amino acid may be distinguished by immunological means.

From these experiments, von Behring inferred the existence of corpuscles (“Antikörper”), or antibodies, as the transferable factor responsible for protection. The antibody-containing (immune) sera not only afforded protection *in vivo*, they also killed microbes in the test tube (Figure 23-7, *right*). Heating the immune sera to 56 °C destroyed this killing activity, but it was restored by the addition of unheated fresh serum from naive animals (i.e., animals never exposed to the microbe). This finding suggested that a second factor, now called complement, acts in synergy with antibodies to kill bacteria. We now know that von Behring’s antibodies are serum proteins referred to as **immunoglobulins** and that complement is actually the series of proteases described above, which carry out pathogen destruction (see Figure 23-4). Immunoglobulins can neutralize not only bacterial toxins but also harmful agents such as viruses, by binding directly to them in a manner that prevents the virus from attaching itself to host cells. In the same vein, antibodies raised against snake venoms can be administered to the victims of snake bites to protect them from intoxication: the anti-snake venom antibodies bind to the venom, keep it from binding to its targets in the host, and in so doing neutralize it. This is called passive immunization, a procedure that can save lives by instant neutralization of a noxious substance such as a toxin. Antibodies can thus have immediate protective effects. Where today’s medical advances allow the survival of individuals whose immune system is severely compromised (cancer patients receiving chemotherapy and/or radiation, transplant patients with a pharmacologically suppressed immune system, patients who suffer from HIV/AIDS, individuals with inborn deficiencies of their immune system), passive immunization can be of immediate practical importance.

EXPERIMENTAL FIGURE 23-7 The existence of antibody in serum from infected animals was demonstrated by von Behring and Kitasato. Exposure of animals to a sublethal dose of diphtheria toxin (or the bacteria that produce it) elicits in their serum a substance that protects against a subsequent challenge with a lethal dose of the toxin (or the bacteria that produce it). The protective effect of this serum substance can be transferred from an animal that has been exposed to the pathogen to a naive (nonexposed) animal. When the serum recipient is subsequently exposed to a lethal dose of the

bacteria, the animal survives. This effect is specific for the pathogen used to elicit the response. Serum thus contains a transferable substance (antibody) that protects against the harmful effects of a virulent pathogen. Serum harvested from these animals, said to be immune, displays bactericidal activity in vitro. Heating of immune serum destroys its bactericidal activity. Addition of fresh nonheated serum from a naive animal restores the bactericidal activity of heated immune serum. Serum thus contains another substance that complements the activity of antibodies.

KEY CONCEPTS of Section 23.1

Overview of Host Defenses

- Mechanical and chemical defenses provide protection against most pathogens. This protection is immediate and continuous, yet possesses little specificity. Innate and adaptive immunity provide defenses against pathogens that breach the body's mechanical/chemical boundaries (see Figure 23-1).
- The circulatory and lymphatic systems distribute the molecular and cellular players in innate and adaptive immunity throughout the body (see Figure 23-2).
- Innate immunity is mediated by the complement system (see Figure 23-4) and several types of leukocytes, the most important of which are neutrophils and other phagocytic

cells such as macrophages and dendritic cells. The cells and molecules of innate immunity are deployed rapidly (minutes to hours). Molecular patterns diagnostic of the presence of pathogens can be recognized by Toll-like receptors, but the specificity of recognition is modest.

- Adaptive immunity is mediated by T and B lymphocytes. These cells require days for full activation and deployment, but they can distinguish between closely related antigens. This specificity of antigen recognition is the key distinguishing feature of adaptive immunity.
- Innate and adaptive immunity act in a mutually synergistic fashion. Inflammation, an early response to tissue injury or infection, involves a series of events that combines elements of innate and adaptive immunity (see Figure 23-6).

23.2 Immunoglobulins: Structure and Function

Immunoglobulins, produced by B cells, are the best-understood molecules that confer adaptive immunity. In this section we describe the overall structural organization of immunoglobulins, their structural diversity, and how they bind to antigens.

Immunoglobulins Have a Conserved Structure Consisting of Heavy and Light Chains

Like complement, immunoglobulins are abundant serum proteins that can be classified in terms of their structural and functional properties. Fractionation of antisera, based on their functional activity (e.g., killing of microbes, binding of antigen), led to the identification of the immunoglobulins as the class of serum proteins responsible for antibody activity. Immunoglobulins are composed of two identical *heavy (H) chains*, covalently attached to two identical *light (L) chains* (Figure 23-8). The typical immunoglobulin therefore has a twofold-symmetrical structure, described as H_2L_2 . An exception to this basic H_2L_2 architecture occurs in the camelids (camels, llamas, vicuñas). These animals can make some immunoglobulins that are heavy-chain dimers (H_2) and lack light chains.

A biochemical approach was used to answer the question of how antibodies manage to distinguish between related antigens. Proteolytic enzymes were used to fragment immunoglobulins, which are rather large proteins, to identify the regions directly involved in antigen binding (see Figure 23-8). The protease papain yields monovalent fragments, called $F(ab)$, that can bind a single antigen molecule, whereas the protease pepsin yields bivalent fragments, referred to as $F(ab')_2$ (F = fragment; ab = antibody). These enzymes are commonly used to convert intact immunoglobulin molecules into monovalent or bivalent reagents. Although $F(ab)$ fragments are incapable of cross-linking antigen, $F(ab')_2$ fragments can do so, a property frequently used to cross-link and so activate surface receptors; many receptors such as the EGF receptor dimerize upon engagement of ligand, a prerequisite for full activation of downstream signaling cascades. The portion released upon papain digestion and incapable of antigen binding is called F_c , because of its ease of crystallization (F = fragment; c = crystallizable). This biochemical approach using proteases was followed by peptide mapping

and sequencing strategies to determine the primary structure of the immunoglobulins.

Multiple Immunoglobulin Isotypes Exist, Each with Different Functions

Based on their distinct biochemical properties, immunoglobulins are divided into different classes, or *isotypes*. There are two light-chain isotypes, κ and λ . The heavy chains show more variation: in mammals, the major heavy-chain isotypes are μ , δ , γ , α , and ϵ . These heavy chains can associate with either κ or λ light chains. Depending on the vertebrate species, further subdivisions occur for the α and γ chains, and fish possess an isotype that is not found in mammals. The fully assembled immunoglobulin (Ig) derives its name from the heavy chain: μ chains yield IgM; α chains, IgA; γ chains, IgG; δ chains, IgD; and ϵ chains, IgE. The general structures of the major Ig isotypes are depicted in Figure 23-9. By means of unique structural features of their F_c portions, each of the different Ig isotypes carries out specialized functions.

The IgM molecule is secreted as a pentamer, stabilized by disulfide bonds and an additional chain, the J chain. In its pentameric form, IgM possesses 10 identical antigen-binding sites, which allow high-avidity interactions with surfaces that display the corresponding (cognate) antigen. Avidity is defined as the sum total of the *strength* of interactions (affinity)

FIGURE 23-8 The basic structure of an immunoglobulin molecule.

Antibodies are serum proteins also known as immunoglobulins. They are twofold-symmetrical structures composed of two identical heavy chains and two identical light chains. Fragmentation of antibodies with proteases yields fragments that retain antigen-binding capacity. The protease papain yields monovalent $F(ab)$ fragments, and the protease pepsin yields bivalent $F(ab')_2$ fragments. The F_c fragment is unable to bind antigen, but this portion of the intact molecule has other functional properties.

FIGURE 23-9 Immunoglobulin isotypes. The different classes of immunoglobulins, called isotypes, may be distinguished biochemically and by immunological techniques. In mouse and humans there are two light-chain isotypes (κ and λ) and five heavy-chain isotypes (μ , δ , γ , ϵ , α). Based on the identity of the heavy chain, each isotype defines a class of immunoglobulin. IgG, IgE, and IgD (not shown) are monomers with generally similar overall structures. IgM and IgA are unusual

because they can occur in serum as pentamers and dimers, respectively, accompanied by an accessory subunit, the J chain, in covalent disulfide linkage. The volume-rendered depiction of the immunoglobulins highlights their modular design, with each barrel representing an individual Ig domain. Different isotypes have different functions. See Figure 23-12 for definitions of abbreviations.

of the available individual binding sites and the *number* of such binding sites. Upon deposition of IgM onto a surface that carries the antigen, the pentameric IgM molecule assumes a conformation that is highly conducive to activation of the complement cascade, an effective means of damaging the membrane onto which IgM is adsorbed and onto which complement proteins are deposited as a consequence.

The IgA molecule also interacts with the J chain, forming a dimeric structure. Dimeric IgA can bind to the polymeric IgA receptor on the basolateral side of epithelial cells, where its engagement results in receptor-mediated endocytosis. Subsequently, the IgA receptor is cleaved and dimeric IgA with the proteolytic receptor fragment (secretory piece) still attached is released from the apical side of the epithelial cell. This process, called **transcytosis**, is an effective means of delivering immunoglobulins from the basolateral side of an epithelium to the apical side (Figure 23-10a). Tear fluid and other secretions are rich in IgA and so provide protection against environmental pathogens.

The IgG isotype is important for neutralization of virus particles. This isotype also helps prepare particulate antigens for acquisition by cells equipped with receptors specific for the Fc portion of IgG molecules (see below).

The immune system of the newborn is immature, and mammals transfer protective antibodies from the mother to the fetus via the mother's milk. The receptor responsible for capturing maternal IgG is the neonatal Fc receptor (FcRn), which is present on intestinal epithelial cells in rodents. By transcytosis, IgG captured on the luminal side of the

newborn's intestinal tract is delivered across the gut epithelium and so makes maternal antibodies in the milk available for passive protection of the infant rodent (Figure 23-10b). In humans, FcRn is found on fetal cells that contact the maternal circulation in the placenta. Transcytosis of IgG antibodies from the maternal circulation across the placenta delivers maternal antibodies to the fetus. These maternal antibodies will protect the newborn until its own immune system is sufficiently mature to produce antibodies under its own steam. In adults, FcRn is also expressed on endothelial cells and helps control the turnover of IgG in the circulation.

As we will see in Section 23.3, the IgM and IgD isotypes are expressed as membrane-bound B-cell receptors on newly generated B cells. Here the μ chains have an important role in B-cell development and activation.

Each B Cell Produces a Unique, Clonally Distributed Immunoglobulin

The *clonal selection theory* stipulates that each lymphocyte carries an antigen-binding receptor of unique specificity. When a lymphocyte encounters the antigen for which it is specific, clonal expansion (rapid cell division) occurs and so allows an amplification of the response, culminating in clearing of the antigen (Figure 23-11). In a typical immune response, the antigen that elicits the response is of complex composition: even the simplest virus contains several distinct proteins. Many individual lymphocytes respond to a given antigen and expand in response to it, each producing its own antigen receptor of

(a)

(b)

FIGURE 23-10 Transcytosis of IgA and IgG. (a) IgA, found in secretions of the different mucosae, requires transport across the epithelium. IgA binds to the polymeric IgA receptor and is endocytosed. After being transported across the epithelial monolayer, a portion of the receptor is cleaved, and the IgA is released at the apical side together with a portion of the receptor, the secretory piece. (b) Suckling rodents acquire Ig from mother's milk. The newborn possesses at the apical surface of its intestinal epithelium the neonatal Fc receptor (FcRn), whose structure resembles that of class I MHC molecules (see Figure 23-21). After this receptor binds to the Fc portion of IgG, transcytosis moves the acquired IgG to the basolateral side of the epithelium. In humans, the syncytial trophoblast in the placenta expresses FcRn and so mediates acquisition of IgG from the maternal circulation and delivery to the fetus (transplacental transport).

Activation of B cell

FIGURE 23-11 Clonal selection. The clonal selection theory proposes the existence of a large set of lymphocytes, each equipped with its own unique antigen-specific receptor (indicated by different colors). The antigen that fits with the receptor carried by a particular lymphocyte allows that lymphocyte to expand clonally. From a modest number of antigen-specific cells, a large number of cells of the desired specificity (and large amounts of their secreted outputs) may be generated.

unique structure and therefore with unique binding characteristics (affinity). Because each lymphocyte is endowed with a unique receptor and clonally expands in response to antigen, this response is called *polyclonal*.

B-cell tumors, which represent malignant clonal expansions of individual lymphocytes, enabled the first molecular analysis of the processes that underlie the generation of antibody diversity. A key observation was that tumors derived from lymphocytes may produce large quantities of secreted immunoglobulins. Some of the light chains of the immunoglobulins are secreted in the urine of tumor-bearing patients. These light chains, called *Bence-Jones proteins* after their discoverers, are readily purified and afforded the first target for a protein chemical analysis.

Two key observations emerged from this work: (1) no two tumors produced light chains of the identical biochemical properties, suggesting that they were all unique in sequence; and (2) the differences in amino acid sequence that distinguish one light chain from another are not randomly distributed but occur clustered in a domain referred to as the *variable region of the light chain*, or V_L . This domain comprises the N-terminal ≈ 110 amino acids. The remainder of the sequence is identical for the different light chains (provided they derive from the identical isotype, κ or λ) and is therefore referred to as the *constant region*, or C_L . From the serum of tumor-bearing individuals, immunoglobulins unique to that individual patient were subsequently purified.

FIGURE 23-12 Hypervariable regions and the immunoglobulin fold. (a) Variation in amino acid variability with residue position in Ig light chains. The percentage of variable-region sequences with variant amino acids is plotted for each position in the sequence. Positions for which many different amino acid side chains are present in the data set are assigned a high variability index; those that are invariant among the sequences compared are assigned a value of 0. This analysis reveals three regions of increased variability, hypervariability (HV) regions 1, 2, and 3; these are also called complementarity-determining regions (CDRs). (b) Volume-rendered depiction of $F(ab')_2$ fragment (right) and ribbon diagram of a typical Ig light-chain variable domain (V_L) with the positions of the hypervariable regions indicated in red (left). The hypervariable regions are found in the loops that connect the β strands and make contact with antigen. The β strands (rendered as arrows) make up two β sheets and constitute the framework region. Note that each variable and constant domain has a characteristic three-dimensional structure, called the immunoglobulin fold. L = light chain; H = heavy chain; V_H = heavy-chain variable domain; V_L = light-chain variable domain; C_H1 , C_H2 , C_H3 = heavy-chain constant domains; C_L = light-chain constant domain.

Sequencing of the heavy chains from these preparations revealed that the variable residues that distinguish one heavy chain from another were again concentrated in a well-demarcated domain, referred to as the *variable region of the heavy chain*, or V_H .

An alignment of sequences obtained from different homogeneous light-chain preparations showed a nonrandom pattern of regions of variability, revealing three *hypervariable regions*—HV1, HV2, and HV3—which are sandwiched between what are called *framework regions* (Figure 23-12a). (Similar alignments for the immunoglobulin heavy-chain sequences also yield hypervariable regions.) In the properly folded three-dimensional structure of immunoglobulins, these hypervariable regions are in close proximity (Figures 23-12b and 23-13) and make contact with antigen. Thus that portion of an Ig molecule containing the hypervariable regions constitutes the antigen-binding site. For this reason, hypervariable regions are also referred to as *complementarity-determining regions* (CDRs).

The difficulty of encoding in the germ line all of the information necessary to generate this enormously diverse antibody repertoire led to suggestions of unique genetic mechanisms to account for this diversity. Perhaps as many as a million different antibodies of unique specificity might be required to afford reasonable protection against the multi-

tude of pathogens we confront in the course of a lifetime, although such estimates remain guesswork at best. Given the size of a typical antibody heavy chain and light chain (each heavy chain-light chain combination, if encoded as such, would require ≈ 2.5 – 3.5 kb, depending on the isotype), it is immediately obvious that the organism would rapidly exhaust the DNA coding capacity required to encode a set of antibody molecules of sufficient diversity to provide adequate protection against the wide array of pathogens and other foreign substances to which the organism is exposed. We shall see that, indeed, unique mechanisms are at work to create an adequately diverse set of antibodies.

Immunoglobulin Domains Have a Characteristic Fold Composed of Two β Sheets Stabilized by a Disulfide Bond

Both the variable and constant domains of immunoglobulins fold into a compact three-dimensional structure composed exclusively of β sheets (see Figure 23-12b). A typical Ig domain contains two β sheets (one with three strands and one with four strands) held together by a disulfide bond. The residues that point inward are mostly hydrophobic and help stabilize this sandwich structure. Solvent-exposed residues show a greater frequency of polar and charged side chains. The spacing of the cysteine residues that make up the disulfide bond and a small number of strongly conserved residues characterize this evolutionarily ancient structural motif, termed the *immunoglobulin fold*. The basic immunoglobulin fold is found in numerous eukaryotic proteins that are not directly involved in antigen-specific recognition, including the Ig superfamily of cell-adhesion molecules, or IgCAMs (Chapter 20).

FIGURE 23-13 Immunoglobulin structure. This model shows the three-dimensional structure of an immunoglobulin complexed with hen

egg-white lysozyme (a protein antigen) as determined by x-ray crystallography. [Based on E. A. Padlan et al., 1989 *Proc. Natl Acad. Sci USA* **86**:5938.]

The region on an antigen where it makes contact with the corresponding antibody is called an **epitope**. A protein antigen usually contains multiple epitopes, which often are exposed loops or surfaces on the protein and thus accessible to antibody molecules. Each homogeneous antibody preparation, derived from a clonal population of B cells, recognizes a single molecularly defined epitope on the corresponding antigen.

In order to solve the structure of an antibody complexed to its cognate epitope on an antigen, it is important to have a source of homogeneous immunoglobulin and the antigen in pure form. Homogeneous immunoglobulins can be obtained from B-cell tumors (malignant monoclonal expansions of immunoglobulin-secreting B cells), but in that case the antigen for which the antibody is specific is not known. The breakthrough essential for generating homogeneous antibody preparations suitable for structural analysis was the development of techniques to obtain **monoclonal antibody** produced by **hybridomas** by use of a special selection medium (see Chapter 9, pp. 402–404). The creation of immortalized cell lines that produce antibodies of defined specificity (monoclonal antibodies) has yielded essential tools for the cell biologist: monoclonal antibodies are widely used for the specific detection of macromolecules and their modifications. Monoclonal antibodies can detect proteins and their modifications (phosphorylation, nitrosylation, methylation, acetylation, etc.), complex carbohydrates, (glyco)lipids, nucleic acids, and their modifications, and have therefore found widespread use in the laboratory as well as for diagnostic purposes.

We now have detailed insights into the structure of a large number of monoclonal antibodies in complex with the antigen for which they are specific. There are no hard-and-fast rules that describe these interactions, other than that the usual rules of interaction of proteins with other (macro)molecules

apply (see Chapter 3). The CDRs make the most important contributions to the antigen-antibody interface, with a particularly prominent role for the CDR3 of the Ig heavy chain, followed by the CDR3 of the Ig light chain. How diversity is created in the CDRs will be described below.

An Immunoglobulin's Constant Region Determines Its Functional Properties

Antibodies recognize antigen via their variable regions, but their constant regions determine many of the functional properties of antibodies. An important functional property of antibodies is their neutralizing capacity. By binding to epitopes on the surface of virus particles or bacteria, antibodies may block a productive interaction between a pathogen and receptors on host cells, thereby inhibiting (neutralizing) infection.

Antibodies attached to a virus or microbial surface can be recognized directly by cells that express receptors specific for the Fc portion of immunoglobulins. These *Fc receptors* (FcRs), which are specific for individual classes and subclasses of immunoglobulins, display considerable structural and functional heterogeneity. By means of FcR-dependent events, specialized phagocytic cells such as dendritic cells and macrophages can engage antibody-decorated particles, then ingest and destroy them in the process of opsonization. FcR-dependent events also allow some immune-system cells (e.g., monocytes and natural killer cells) to directly engage target cells that display viral or other antigens to which antibodies are attached. This engagement may induce the immune-system cells to release toxic small molecules (e.g., oxygen radicals) or the contents of cytotoxic granules, including perforins and granzymes. These proteins can attach themselves to the surface of the engaged target cell, inflict membrane damage, and so kill the target (see

Figure 23-5). This process, called *antibody-dependent cell-mediated cytotoxicity*, illustrates how cells of the innate immune system interact with, and benefit from, the products of the adaptive immune response.

Depending on the immunoglobulin isotype, antigen-antibody (immune) complexes can initiate the classical pathway of complement activation (see Figure 23-4). IgM and IgG3 are particularly good at complement activation, but all IgG classes can in principle activate complement, whereas IgA and IgE are unable to do so.

KEY CONCEPTS of Section 23.2

Immunoglobulins: Structure and Function

- Most immunoglobulins (antibodies) are composed of two identical heavy (H) chains and two light (L) chains, with each chain containing a variable (V) region and a constant (C) region. Proteolytic fragmentation yields monovalent F(ab) and bivalent F(ab')₂ fragments, which contain variable-region domains and retain antigen-binding capability (see Figure 23-8). The Fc portion contains constant-region domains and determines effector functions.
- Immunoglobulins are divided into classes based on the constant regions of the heavy chains they carry (see Figure 23-9). In mammals there are five major classes: IgM, IgD, IgG, IgA, and IgE; the corresponding heavy chains are referred to as μ , δ , γ , α , and ϵ . There are two major classes of light chain, κ and λ , again characterized by the attributes of their constant regions.
- Each individual B lymphocyte expresses an immunoglobulin of unique sequence and is therefore uniquely specific for a particular antigen. Upon recognition of antigen, only a B lymphocyte that bears a receptor specific for it will be activated and expand clonally (clonal selection) (see Figure 23-11).
- The antigen specificity of antibodies is conferred by their variable domains, which contain regions of high variability, called hypervariable or complementarity-determining regions (see Figure 23-12a). These hypervariable regions are positioned at the tip of the variable domain, where they can make specific contacts with the antigen for which a particular antibody is specific.
- The repeating domains that make up immunoglobulin molecules have a characteristic three-dimensional structure, the immunoglobulin fold: it consists of two β pleated sheets held together by a disulfide bond (see Figure 23-12b). The immunoglobulin fold is widespread in evolution and is found in many proteins other than antibodies, including an important class of cell-adhesion molecules.
- The constant regions endow antibodies with unique functional properties or effector functions, such as the capacity to bind complement, the ability to be transported across epithelia, or the ability to interact with receptors specific for the Fc portion of immunoglobulins.

23.3 Generation of Antibody Diversity and B-Cell Development

Pathogens have short replication times, are quite diverse in their genetic makeup, and evolve quickly, generating even more antigenic variation. An adequate defense must thus be capable of mounting an equally diverse response. Antibodies fulfill this role. The timing of the antibody response and its necessary adjustment to changes in the antigenic makeup of the pathogen in question pose unique demands on the organization and regulation of the adaptive immune system. The coding capacity of the typical vertebrate genome could not possibly encode the large number of antibodies required for adequate protection against the diversity of microbes to which the host is exposed. A unique mechanism evolved to allow not only sheer limitless variability of the antibody repertoire, but also to enable rapid adjustment of the quality of the antibodies produced, to meet the demands posed by an unfolding viral or bacterial infection. Because optimal antibody production requires assistance in the form of T-cell help, we shall see that molecular mechanisms underlying receptor diversity are fundamentally similar for B and T cells.

B cells, which are responsible for antibody production, make use of a unique mechanism by which the genetic information required for synthesis of immunoglobulin heavy and light chains is stitched together from separate DNA sequence elements, or Ig gene segments, to create a functional transcriptional unit. The act of recombination that combines Ig gene segments itself dramatically expands the variability in sequence precisely where these genetic elements are joined together. This mechanism of generating a diverse array of antibodies is fundamentally different from meiotic recombination, which occurs only in germ cells, and from alternative splicing of exons (Chapter 8). Because this recombination mechanism occurs in somatic cells but not in germ cells, it is known as *somatic gene rearrangement* or *somatic recombination*. This unusual recombination mechanism, unique to antigen receptors on B and T lymphocytes, makes it possible to specify an enormously diverse set of receptors with minimal expenditure of DNA coding space. The ability to combine at will discrete genetic elements (combinatorial diversity), in addition to the generation of yet more sequence diversity in the encoded receptors by the underlying recombination mechanisms themselves, allows adaptive immune responses against a virtually limitless array of antigens, including molecules encoded by the host.

Thus there are mechanisms at work that not only create this enormous diversity, but there are also processes that impose tolerance to curtail unwanted reactivity against “self” components; the result of such reactivity is autoimmunity. Neither mechanism is perfect: the adaptive immune system cannot generate receptors to see *all* foreign substances. Furthermore, the unavoidable price we pay for *how* we generate B- and T-cell receptors is the likelihood of self-reactive receptors (auto-immunity).

A Functional Light-Chain Gene Requires Assembly of V and J Gene Segments

Immunoglobulin genes encoding intact immunoglobulins do not exist already assembled in the genome, ready for expression. Instead, the required gene segments are brought together and assembled in the course of B-cell development (Figure 23-14). Although the rearrangement of heavy-chain genes precedes the rearrangement of light-chain genes, we discuss light-chain genes first because of their less complex organization.

The immunoglobulin light chains are encoded by clusters of V gene segments, followed at some distance downstream by a single C segment. Each V gene segment carries its own promoter sequence and encodes the bulk of the light-chain variable region, although a small piece of the nucleotide sequence encoding the light-chain variable region is missing from the V gene segment. This missing portion is provided by one of the multiple J segments located between the V segments and the single C segment in the unrearranged κ light-chain locus (see Figure 23-14a). This J segment is a genetic element, not to be confused with the J chain, a polypeptide subunit of the pentameric IgM molecule and found also in association with IgA (see Figure 23-9). In the course of B-cell development, commitment to a particular V gene segment—a random process—results in its juxtaposition with one of the J segments, again a random choice, forming an exon encoding the entire light-chain variable region (V_L). The act of recombination not only generates an intact and functional light-chain gene, it also places the promoter sequence of the rearranged gene within

controlling distance of enhancer elements, located downstream of the light-chain constant-region exon, required for its transcription. Only a rearranged light-chain gene is transcribed.

Recombination Signal Sequences Detailed sequence analysis of the light-chain and heavy-chain loci revealed a conserved sequence element at the 3' end of each V gene segment. This conserved element, called a *recombination signal sequence* (RSS), is composed of heptamer and nonamer sequences separated by a 23-bp spacer. At the 5' end of each J element, there is a similarly conserved RSS that contains a 12-bp spacer (Figure 23-15a). The 12- and 23-bp spacers separate the conserved heptamer and nonamer sequences by one and two turns of the DNA helix, respectively.

Somatic recombination is catalyzed by the RAG1 and RAG2 recombinases, which are expressed only in lymphocytes. Juxtaposition of the two gene segments to be joined is stabilized by the RAG1/RAG2 complex (Figure 23-15b). The recombinases then make a single-stranded cut at the exact boundary of each coding sequence and its adjacent RSS. Only gene segments that possess heptamer-nonamer RSSs with spacers of different lengths can engage in this type of rearrangement (the so-called 12/23-bp spacer rule). Each newly created —OH group at the site of cleavage then executes a nucleophilic attack on the complementary strand, creating a covalently closed hairpin for each of the two coding ends, and double-strand breaks at the ends of the RSSs. Protein complexes that include the Ku70 and Ku80 proteins hold this complex together, so that the ends about to be

FIGURE 23-14 Overview of somatic gene rearrangement in immunoglobulin DNA. The stem cells that give rise to B cells contain multiple gene segments encoding portions of immunoglobulin heavy and light chains. During development of a B cell, somatic recombination of these gene segments yields functional light-chain genes (a) and heavy-chain genes (b). Each V gene segment carries its own promoter. Rearrangement brings an enhancer close enough to the combined sequence to activate transcription. The light-chain variable region (V_L)

is encoded by two joined gene segments, and the heavy-chain variable region (V_H) is encoded by three joined segments. Note that the chromosomal regions encoding immunoglobulins contain many more V, D, and J segments than shown. Also, the κ light-chain locus contains a single constant (C) segment, as shown, but the heavy-chain locus contains several distinct C segments (not shown) corresponding to the immunoglobulin isotypes.

joined remain in close proximity: double-strand breaks in chromosomes need to be repaired, and thus the ends need to be held together for resolution and repair of these breaks to proceed. The RSS ends are then covalently joined without loss or addition of nucleotides, creating a circular reaction product (deletion circle) containing the intervening DNA, which is lost from the locus altogether. The hairpin ends of the coding segments undergoing recombination then are opened and finally joined as depicted in Figure 23-15c, completing the recombination process.

The recombination mechanism just described, called *deletional joining*, occurs when the V gene segment involved has the same transcriptional orientation as the other gene segments at the light-chain locus. Some V gene segments, however, have the opposite transcriptional orientation. These are joined to J segments by a mechanism, termed *inversional joining*, in which the V segment is inverted and the intervening DNA and RSSs are not lost from the locus.

Defects in the synthesis of RAG proteins obliterates the possibility of somatic gene rearrangements. As described below, the rearrangement process is essential for B-cell development; consequently, RAG deficiency leads to the complete absence of B cells. People with defects in RAG gene function suffer from severe immunodeficiency. Targeted deletion of RAG genes in mice likewise leads to a complete defect in immunoglobulin (and T-cell receptor) gene rearrangement, resulting in a developmental block in the generation of B and T lymphocytes.

Junctional Imprecision In addition to the sequence variability created by the random selection of V and J gene segments to join, processing of the intermediates created in the course of recombination provides additional means for expanding the variability of immunoglobulin sequences. This additional variability is created at the junction of the segments to be joined. The opening of the hairpins at the coding ends is a key step in this process: this opening may occur symmetrically or asymmetrically (see Figure 23-15c, **4** and **5**). The protein Artemis, whose function requires the catalytic subunit of DNA-dependent protein kinase, carries out opening of the hairpins.

If opening of a hairpin is asymmetric, a short, single-stranded palindrome sequence is generated. Filling in of this overhang by DNA polymerase results in the addition of several nucleotides, called *P-nucleotides*, that were not part of the original coding region of the gene segment in question. Alternatively, the overhang may be removed by exonucleolytic attack, resulting in the removal of nucleotides from the original coding region. These possibilities apply equally to the V and the J coding regions. Symmetric opening of a hairpin retains all the original coding information. However, even if the hairpin is opened symmetrically, the ends of the DNA molecule tend to breathe, creating short single-stranded sequences, which also may be attacked exonucleolytically, resulting in removal of nucleotides.

Once the hairpins have been opened and the coding ends processed, the ends are ligated together by DNA ligase IV and

XRCC4, generating a functional light-chain gene. Inherent in the rearrangement process is *junctional imprecision* resulting in part from the addition and loss of nucleotides at the coding joints. Whenever a V and a J segment recombine, the sequence and reading frame of the VJ product cannot be predicted. Only one in three recombination reactions results in a reading frame that is compatible with light-chain synthesis.

Light-chain diversity therefore arises not only from the combinatorial usage of V and J gene segments, but also from junctional imprecision. Inspection of the three-dimensional structure of the light chain shows that the highly diverse joint, generated as a consequence of junctional imprecision, forms part of a loop—hypervariable region 3 (HV3)—that projects into the antigen-binding site and makes contact with antigen (see Figure 23-12b).

Rearrangement of the Heavy-Chain Locus Involves V, D, and J Gene Segments

The organization of the heavy-chain locus is more complex than that of the κ light-chain locus. The heavy-chain locus contains not only a large tandem array of V gene segments (each equipped with its own promoter) and multiple J elements, but also multiple D (diversity) segments (see Figure 23-14b). Somatic recombination of a V, D, and J segment generates a rearranged sequence encoding the heavy-chain variable region (V_H).

At the 3' end of each V gene segment in heavy-chain DNA, there are conserved heptamer and nonamer sequences separated by spacer DNA, similar to the recombination signal sequences (RSSs) in light-chain DNA. These RSSs are also found in complementary and antiparallel configuration at the 5' end and the 3' end of each D segment (see Figure 23-15a). The J segments are similarly equipped at their 5' end with the requisite RSS. The spacer lengths in these RSSs are such that D segments can join to J segments, and V segments to already rearranged DJ segments. However, neither direct V-to-J nor D-to-D joining is allowed, in compliance with the 12/23 heptamer-nonamer rule. Heavy-chain rearrangements proceed via the same mechanisms described above for light-chain rearrangements.

In the course of B-cell development, the heavy-chain locus always rearranges first, starting with D-J rearrangements. D-J rearrangement is followed by V-DJ rearrangement. In the course of D-J and V-DJ rearrangements, terminal deoxynucleotidyltransferase (TdT) may add nucleotides to free 3' OH ends of DNA in a template-independent fashion. Up to a dozen or so nucleotides, called the *N-region*, may be added, generating additional sequence diversity at the junctions whenever D-J and V-DJ rearrangements occur (see Figure 23-15, step **7**). Only one in three rearrangements yields the proper reading frame for the rearranged VDJ sequence. If the rearrangement yields a sequence encoding a functional protein, it is called *productive*. Although the heavy-chain locus is present on two homologous chromosomes, only one productive rearrangement is permitted, as discussed below.

FIGURE 23-15 Mechanism of rearrangement of immunoglobulin gene segments via deletional joining. This example depicts joining of a V segment and a J segment, as occurs at the light-chain locus (see Figure 23-14a). (a) Location of the DNA elements involved in somatic recombination of immunoglobulin gene segments at the light-chain locus (top) and at the heavy-chain locus (bottom). D segments are present in the heavy-chain, but not light-chain, locus. At the 3' end of all V gene segments is a conserved recombination signal sequence (RSS) composed of a heptamer, a 12-bp spacer, and a nonamer. Each of the J or D segments with which a V can recombine possesses at its 5' end a similar RSS with a 23-bp spacer. The nonamer and heptamer sequences at the 5' end of J or D are complementary and antiparallel to those found at the 3' end of each V when read on the same (top) strand. A similar arrangement exists for the RSS at the 3' end of D and 5' end of J at the heavy-chain locus. (b) Hypothetical model of how two coding regions to be joined may be arranged spatially, stabilized by the RAG1 and RAG2 recombinase complex. Both strands of the DNA are shown. (c) Events in joining of V and J coding regions. The germ-line DNA (1) is folded, bringing the segments to be joined close together, and the RAG1/RAG2 complex makes single-stranded cuts at the boundaries between the coding sequences and RSSs (2). The free 3' —OH groups attack the complementary strands, creating a covalently closed hairpin at each coding end and a clean double-stranded break at each boundary with an RSS (3). The hairpins are opened, either symmetrically (4), as shown for the J segment, or asymmetrically (5), as shown for the V segment. Terminal deoxynucleotidyl transferase adds nucleotides in a template-independent manner to symmetrically opened hairpins (6, right), generating an overhang (yellow) of unpaired nucleotides of random sequence; asymmetric opening automatically creates a palindromic overhang (6, left). The unpaired overhangs at the ends of both the V and D coding regions are filled in by DNA polymerase (7) or may be excised by an exonuclease. DNA ligase IV joins the two segments generated from the V and J coding regions (8). Rearrangements of heavy-chain D and J segments, and V and DJ segments, occur by the same mechanism except that N-region addition does not take place. See text for additional discussion.

An enhancer located downstream of the cluster of J segments and upstream of the μ constant-region segment activates transcription from the promoter at the 5' end of the rearranged VDJ sequence (see Figure 23-14). Splicing of the primary transcript produced from the rearranged heavy-chain gene generates a functional mRNA encoding the μ heavy chain. For both immunoglobulin heavy- and light-chain genes, somatic recombination places the promoters upstream of the V segments within functional reach of the enhancers necessary to allow transcription, so that only rearranged VJ and VDJ sequences, and not the V segments that remain in the germ-line configuration, are transcribed.

Somatic Hypermutation Allows the Generation and Selection of Antibodies with Improved Affinities

In addition to the diversity created by somatic recombination and junctional imprecision, antigen-activated B cells can undergo *somatic hypermutation*. Upon receipt of proper

additional signals, most of which are provided by T cells, expression of activation-induced deaminase (AID) is turned on. This enzyme deaminates cytosine residues to uracil. When a B cell that carries this lesion replicates, it may place an adenine on the complementary strand, thus generating a G-to-A transition (see Figure 4-35). Alternatively, the uracil may be excised by DNA glycosylase to yield an abasic site. These abasic sites, when copied, give rise to possible transitions as well as a transversion, unless the nucleotide opposite the gap is chosen to be the original G that paired with the cytosine target. Mutations thus accumulate with every successive round of B-cell division, yielding numerous mutations in the rearranged VJ and VDJ segments. Many of these mutations are deleterious, in that they reduce the affinity of the encoded antibody for antigen, but some improve the encoded antibody's affinity for antigen. B cells carrying affinity-increasing mutations have a selective advantage when they compete for the limited amount of antigen that evokes clonal selection (see Figure 23-11). The net result is generation of a B-cell population whose antibodies, as a rule, show a higher affinity for the antigen.

In the course of an immune response or upon repeated immunization, the antibody response exhibits *affinity maturation*, an increase in the average affinity of antibodies for antigen, as the result of somatic hypermutation. Antibodies produced during this phase of the immune response display affinities for antigen in the nanomolar (or better) range. For reasons that are not understood, the activity of activation-induced deaminase is focused mostly on rearranged VJ and VDJ segments, and this targeting may therefore require active transcription. The entire process of somatic hypermutation is strictly antigen-dependent and shows an absolute requirement for interactions between the B cell and certain T cells.

B-Cell Development Requires Input from a Pre-B-Cell Receptor

As we have seen, B cells destined to make immunoglobulins must rearrange the necessary gene segments to assemble functional heavy- and light-chain genes. These rearrangements occur in a carefully ordered sequence during development of a B cell, starting with heavy-chain rearrangements. Moreover, the rearranged heavy chain is first used to build a membrane-bound receptor that executes a cell-fate decision necessary to drive further B-cell development (and antibody synthesis). Only a productive rearrangement that yields an in-frame VDJ combination can generate a complete μ heavy chain. The production of these μ chains serves as a signal to indicate to the B cell that it has successfully accomplished rearrangement, and that no further rearrangements of the heavy-chain locus on the remaining allele are required. Recall that each lymphocyte precursor starts out with two immunoglobulin locus-bearing chromosomes in the germ-line configuration. In accordance with clonal selection theory, which stipulates that each lymphocyte ought to come equipped with a single antigen-specific receptor, continued

rearrangement would entail the risk of producing B cells with two different heavy chains, each with different specificity, an undesirable outcome.

Successful rearrangement of V, D, and J segments in the heavy-chain locus thus allows synthesis of a complete μ chain. B cells at this stage of development are called *pre-B cells*, as they have not yet completed assembly of a functional light-chain gene and therefore cannot engage in antigen recognition. The newly rearranged heavy-chain gene encodes the μ polypeptide, which becomes part of a signaling receptor whose expression is essential for B-cell development to proceed in orderly fashion. The μ chain made at this stage of B-cell development is a membrane-bound version.

In pre-B cells, newly made μ chains form a complex with two so-called surrogate light chains, $\lambda 5$ and VpreB (Figure 23-16). The μ chain itself possesses no cytoplasmic tail and is therefore incapable of recruiting cytoplasmic components for the purpose of signal transduction. Instead, early B cells express two auxiliary transmembrane proteins, called $Ig\alpha$ and $Ig\beta$, each of which carries in its cytoplasmic tail an im-

munoreceptor tyrosine-based activation motif, or ITAM. The entire complex, including μ chain, $\lambda 5$, VpreB, $Ig\alpha$, and $Ig\beta$, constitutes the *pre-B-cell receptor (pre-BCR)*. Engagement of this receptor by (unknown) suitable signals results in recruitment and activation of a Src-family tyrosine kinase, which phosphorylates tyrosine residues in the ITAMs. In their phosphorylated form, ITAMs recruit other molecules essential for signal transduction (see below). Because no functional light chains are yet part of this receptor, it is presumed to be incapable of antigen recognition.

The pre-B-cell receptor has several important functions. First, it shuts off expression of the RAG recombinases, so rearrangement of the other (allelic) heavy-chain locus cannot proceed. This phenomenon, called *allelic exclusion*, ensures that only one of the two available copies of the heavy-chain locus will be rearranged and thus expressed as a complete μ chain. Second, because of the association of the pre-B-cell receptor with $Ig\alpha$ and $Ig\beta$, the receptor becomes a functional signal-transduction unit. Signals that emanate from the pre-BCR initiate pre-B-cell proliferation to expand the numbers

FIGURE 23-16 Structure of the pre-B-cell receptor and its role in B-cell development. Successful rearrangement of V, D, and J heavy-chain gene segments allows synthesis of membrane-bound μ heavy chains in the endoplasmic reticulum (ER) of a pre-B cell. At this stage, no light-chain gene rearrangement has occurred. Newly made μ chains assemble with surrogate light chains, composed of $\lambda 5$ and VpreB, to yield the pre-B-cell receptor, pre-BCR (step 1). This receptor drives proliferation of those B cells that carry it. It also suppresses rearrangement of the heavy-chain locus on the other chromosome and so

mediates allelic exclusion. In the course of proliferation, the synthesis of $\lambda 5$ and VpreB is shut off (step 2), resulting in "dilution" of the available surrogate light chains and reduced expression of the pre-BCR. As a result, rearrangement of the light-chain loci can proceed (step 3). If this rearrangement is productive, the B cell can synthesize light chains and complete assembly of the B-cell receptor (BCR), comprising a membrane-bound IgM and associated $Ig\alpha$ and $Ig\beta$. The B cell is now responsive to antigen-specific stimulation.

of those B cells that have undergone productive D-J and V-DJ recombination.

In the course of this expansion, expression of the surrogate light-chain subunits, VpreB and $\lambda 5$, subsides. The progressive dilution of VpreB and $\lambda 5$ with every successive cell division allows reinitiation of expression of the RAG enzymes, which now target the κ or λ light-chain locus for recombination. A productive light-chain V-J rearrangement also shuts off rearrangement of the allelic locus (allelic exclusion). Upon completion of a successful V-J light-chain rearrangement, the B cell can make both μ heavy chains and κ or λ light chains, and assemble them into a functional B-cell receptor (BCR), which can recognize antigen (see Figure 23-16).

Once a B cell expresses a complete BCR on its cell surface, it can recognize antigen, and all subsequent steps in B-cell activation and differentiation involve antigen-specific engagement by the antigen for which that BCR is specific. The BCR not only plays a role in driving B-cell proliferation upon successful encounter with antigen, it also functions as a device for capturing and ingesting antigen, an essential step that allows the B cell to process the acquired antigen and convert it into a signal that sends out a call for assistance by T lymphocytes. This antigen-presentation function of B cells is described in later sections.

During an Adaptive Response, B Cells Switch from Making Membrane-Bound Ig to Making Secreted Ig

As just described, the B-cell receptor (BCR), a membrane-bound IgM, provides a B cell with the ability to recognize a particular antigen, an event that triggers clonal selection and

proliferation of that B cell, thus increasing the number of B cells specific for the antigen (see Figure 23-11). However, key functions of immunoglobulins, such as neutralization of antigen or killing of bacteria, require that these products be released by the B cell, so that they may accumulate in the extracellular environment and act at a distance from the site where they were produced.

The choice between the synthesis of membrane-bound versus secreted immunoglobulin is made during processing of the heavy-chain primary transcript. As shown in Figure 23-17, the μ locus contains two exons (TM1 and TM2) that together encode a C-terminal domain that anchors IgM in the plasma membrane. One polyadenylation site is found upstream of these exons; a second polyadenylation site is present downstream. If the downstream poly(A) site is chosen, then further processing yields an mRNA that encodes the membrane-bound form of μ . (As described above, this choice is necessary for formation of the B-cell receptor, which includes membrane-bound IgM.) If the upstream poly(A) site is chosen, processing yields the secreted version of the μ chain. Similar arrangements are found for the other Ig constant-region gene segments, each of which can specify either a membrane-bound or a secreted heavy chain. The ability to switch between the membrane-anchored and the secreted form of immunoglobulin heavy chains by alternative use of poly-adenylation sites (*not* by alternative splicing) is so far unique to this family of gene products.

The capacity to switch from the synthesis of exclusively membrane immunoglobulin to the synthesis of secreted immunoglobulin is acquired by B cells in the course of their differentiation. Terminally differentiated B cells, called *plasma cells*, are devoted almost exclusively to the synthesis

FIGURE 23-17 Synthesis of secreted and membrane IgM. The organization of the μ heavy-chain primary transcript is shown at the top: $C\mu 4$ is the exon encoding the fourth μ constant-region domain; μ_s is a coding sequence unique for secreted IgM; TM1 and TM2 are exons that specify the transmembrane domain of the μ chain. Whether secreted or membrane-bound IgM is made depends on which poly(A) site is selected during processing of the primary transcript. (a) If the

upstream poly(A) site is used, the resulting mRNA includes the entire $C\mu 4$ exon and specifies the secreted form of the μ chain. (b) If the downstream poly(A) site is used, a splice donor site in the $C\mu 4$ exon allows splicing to the transmembrane exons, yielding a mRNA that encodes the membrane-bound form of the μ chain. Similar mechanisms generate secreted and membrane-bound forms of other Ig isotypes. SS = signal sequence.

FIGURE 23-18 Class-switch recombination in the immunoglobulin heavy-chain locus. Class-switch recombination involves switch sites, which are repetitive sequences (colored circles) upstream of the heavy-chain constant-region genes. Recombination requires activation-induced deaminase (AID), assistance by T cells, and cytokines (e.g., IL-4) produced by certain T cells. Recombination eliminates the segment of

DNA between the switch site upstream of μ exons and the constant region to which switching occurs. Class switching generates antibody molecules with the same specificity for antigen as that of the IgM-bearing B cell that mounted the original response, but with different heavy-chain constant-regions and therefore different effector functions.

of secreted antibodies (see Figure 23-6). Plasma cells synthesize and secrete several thousand antibody molecules per second. It is this ramped-up production of secreted antibodies that underlies the effectiveness of the adaptive immune response in eliminating pathogens. The protective value of antibodies is proportional to the concentration at which they are present in the circulation. Indeed, circulating antibody levels are often used as the key parameter to determine whether vaccination against a particular pathogen has been successful. The ability of plasma cells to establish adequate antibody levels is a function of their ability to secrete large amounts of immunoglobulins and so requires a massive expansion of the endoplasmic reticulum, a hallmark of plasma cells. The unfolded protein response (Chapter 13) is initiated in B cells as an essential physiological mechanism to expand the ER and prepare the differentiating B cell for its future task as a highly active secretory cell. Interference with the UPR—for example, by deletion of the XBP1 gene—abolishes the ability of B cells to turn into plasma cells.

B Cells Can Switch the Isotype of Immunoglobulin They Make

In the immunoglobulin heavy-chain locus, the exons that encode the μ chain lie immediately downstream of the rearranged VDJ exon (Figure 23-18, *top*). This is followed by exons that specify the δ chain. Transcription of a newly rearranged immunoglobulin heavy-chain locus yields a single primary transcript that includes the μ and δ constant regions. Splicing of this large transcript determines whether a μ chain or a δ chain will be produced. Downstream of the μ/δ combination are the exons that together encode all of the other heavy-chain isotypes. Upstream of each cluster of exons (with the exception of the δ locus) encoding the different isotypes are repetitive sequences (switch sites) that are recombination-prone, presumably because of their repetitive

nature. Because each B cell necessarily starts out with surface IgM, recombination involving these sites, if it occurs, results in a *class switch* from IgM to one of the other isotypes located downstream in the array of constant-region genes (see Figure 23-18). The intervening DNA is deleted.

In the course of its differentiation, a B cell can switch sequentially. Importantly, the light chain is not affected by this process, nor is the rearranged VDJ segment with which the B cell started out on this pathway. Class-switch recombination thus generates antibodies with different constant regions but identical antigenic specificity. Each immunoglobulin isotype is characterized by its own unique constant region. As discussed previously, these constant regions determine the functional properties of the various isotypes. Class-switch recombination is absolutely dependent on the activity of activation-induced deaminase (AID) and the presence of antigen and T cells. Somatic hypermutation and class-switch recombination occur concurrently, and their combined effect allows fine tuning of the adaptive immune response with respect to the affinity of the antibodies produced and the effector functions called for.

KEY CONCEPTS of Section 23.3

Generation of Antibody Diversity and B-Cell Development

- Functional antibody-encoding genes are generated by somatic rearrangement of multiple DNA segments at the heavy-chain and light-chain loci. These rearrangements involve V and J segments for immunoglobulin light chains, and V, D, and J segments for immunoglobulin heavy chains (see Figure 23-14).
- Rearrangement of the V and J, as well as of the V, D, and J gene segments is controlled by conserved recombination

signal sequences (RSSs), composed of heptamers and nonamers separated by 12- or 23-bp spacers (see Figure 23-15). Only those segments that have spacers of different lengths can rearrange successfully.

- The molecular machinery that carries out the rearrangement process includes recombinases (RAG1 and RAG2) made only by lymphocytes and numerous other proteins that participate in nonhomologous end joining of DNA molecules in other cell types as well.
- Antibody diversity is created by the random selection of Ig gene segments to be recombined (combinatorial joining) and by the ability of the heavy and light chains produced from rearranged Ig genes to associate with many different light chains and heavy chains, respectively (combinatorial association).
- Junctional imprecision generates additional antibody diversity at the joints of the gene segments joined during somatic recombination.
- Further antibody diversity arises after B cells encounter antigen as a consequence of somatic hypermutation, which can lead to the selection and proliferation of B cells producing high-affinity antibodies, a process termed affinity maturation.
- During B-cell development, heavy-chain genes are rearranged first, leading to expression of the pre-B-cell receptor. Subsequent rearrangement of light-chain genes results in assembly of an IgM membrane-bound B-cell receptor (see Figure 23-16).
- Only one of the allelic copies of the heavy-chain locus and of the light-chain locus is rearranged (allelic exclusion), ensuring that a B cell expresses Ig with a single antigenic specificity.
- Polyadenylation of different poly(A) sites in an Ig primary transcript determines whether the membrane-bound or secreted form of an antibody is produced (see Figure 23-17).
- During an immune response, class switching allows B cells to adjust the effector functions of the immunoglobulins produced but retain their specificity for antigen (Figure 23-18).

23.4 The MHC and Antigen Presentation

Antibodies can recognize antigen without the involvement of any third-party molecules; the presence of antigen and antibody is sufficient for their interaction. In the course of their differentiation, B cells receive assistance from T cells, a process that will be described in some detail below. This help is antigen-specific, and the T cells responsible for providing it are *helper T cells*. Although antibodies contribute to the elimination of bacterial and viral pathogens, it is often necessary to destroy also the infected cells that serve as a source of new virus particles. This task is carried out by T cells with cytotoxic activity. These *cytotoxic T cells* and helper T cells make use of antigen-specific receptors whose genes are generated by mechanisms analogous to those used by B cells to generate immunoglobulin genes. However, T cells engage in

antigen recognition in a manner very different from B cells. The antigen-specific receptors on T cells recognize short snippets of protein antigens, presented to these receptors by membrane glycoproteins encoded by the **major histocompatibility complex (MHC)**. Various antigen-presenting cells, in the course of their normal activity, digest pathogen-derived (and self) proteins and then “post” these protein snippets (peptides) to their cell surface in a physical complex with an MHC protein. T cells can inspect these complexes, and if they detect a pathogen-derived peptide, the T cells take appropriate action, which may include killing the cell that carries the MHC-peptide complex. In this section, we describe the MHC and the proteins it encodes, and then examine how these MHC molecules are involved in antigen recognition.

The MHC Determines the Ability of Two Unrelated Individuals of the Same Species to Accept or Reject Grafts

The major histocompatibility complex was discovered, as its name implies, as the genetic locus that controls acceptance or rejection of grafts. At a time when tissue culture had not yet been developed to the stage where tumor-derived cell lines could be propagated in the laboratory, investigators relied on serial passage in vivo of tumor tissue (transplanting a tumor from one mouse to another). It was quickly observed that a tumor that arose spontaneously in one inbred strain of mice could be propagated successfully in the strain in which it arose, but not in a genetically distinct line of mice. Genetic analysis soon showed that a single major locus was responsible for this behavior. Similarly, transplantation of healthy skin was feasible within the same strain of mice, but not when the recipient was of a genetically distinct background. Genetic analysis of transplant rejection likewise identified a single major locus that controlled acceptance or rejection, which is an immune reaction. As we now know, all vertebrates that possess an adaptive immune system have a genetic region that corresponds to the major histocompatibility complex as originally defined in the mouse.

In the mouse, the genetic region that encodes the antigens responsible for a strong graft rejection is called the *H-2 complex* (Figure 23-19a). The initial characterization of the MHC was followed by an appreciation of the genetic complexity of this region. After coarse mapping by standard genetic means (recombination within the MHC), the complete nucleotide sequence of the entire MHC was determined. The typical mammalian MHC contains dozens of genes, many encoding proteins of immunological relevance.

In humans, the discovery of the MHC relied on the characterization of antisera produced in patients who underwent multiple blood transfusions: Antigens expressed on the surface of the genetically nonidentical donor cells provoked an immune response in the recipient. The predominant target antigens recognized by these antisera are encoded by the human MHC, a genetic region also referred to as the *HLA complex* (Figure 23-19b). All vertebrate MHCs encode a highly homologous set

FIGURE 23-19 Organization of the major histocompatibility complex in mice and humans. The major loci are depicted with schematic diagrams of their encoded proteins below. Class I MHC proteins are composed of an MHC-encoded single-pass transmembrane glycoprotein in noncovalent association with a small subunit, called $\beta 2$ -microglobulin, which is not encoded in the MHC and is not membrane bound. Class II MHC proteins consist of two nonidentical single-pass transmembrane glycoproteins, both of which are encoded by the MHC.

of proteins, although the details of organization and gene content show considerable variation between species.

The human fetus may also be considered a graft: The fetus shares only half of its genetic material with the mother, the other half being contributed by the father. Antigens encoded by this paternal contribution may differ sufficiently from their maternal counterparts to elicit an immune response in the mother. Such a response can occur because in the course of pregnancy, fetal cells that slough off into the maternal circulation can stimulate the maternal immune system to mount an antibody response against these paternal antigens. We now know that these antibodies recognize structures encoded by the human MHC. The fetus itself is spared rejection because of the specialized organization of the placenta, which prevents initiation of an immune response by the mother against fetal tissue.

The Killing Activity of Cytotoxic T Cells Is Antigen Specific and MHC Restricted

Clearly, the function of MHC molecules is not to prevent the exchange of surgical grafts. MHC molecules play an essential role in the recognition of virus-infected cells by cytotoxic

T cells; these cells also are called cytotoxic T lymphocytes (CTLs). In virus-infected cells, MHC molecules interact with protein fragments derived from viral pathogens and display these on the cell surface where cytotoxic T cells, charged with eliminating the infection, can recognize them. How such fragments of antigen are generated and displayed for recognition by T cells will be described below. T cells that have receptors of the appropriate specificity unleash a payload of lethal molecules onto the infected target cells, destroying the target cell membrane and so killing the infected target. The destruction of these target cells can be readily measured as the release of their cytoplasmic contents when target cells physically disintegrate.

Mice that have recovered from a particular virus infection are a ready source of cytotoxic T cells that can recognize and kill target cells infected with the same virus. If T cells are obtained from a mouse that successfully cleared an infection with influenza virus, cytotoxic activity is observed against influenza-infected target cells, but not against uninfected controls (Figure 23-20). Moreover, the influenza-specific cytotoxic T cells will not kill target cells infected with a different virus, such as vesicular stomatitis virus. Cytotoxic T cells can even discriminate between closely related strains of influenza virus, and can do so with pinpoint precision: differences of a single amino acid in the viral antigen may suffice to avoid recognition and killing by cytotoxic T cells. These experiments show that cytotoxic T cells are truly antigen specific and do not simply recognize some attribute that is shared by all virus-infected cells, regardless of the identity of the virus.

In this example, it is assumed that the T cells harvested from an influenza-immune mouse are assayed on influenza-infected target cells derived from the identical strain of mouse (strain a). However, if target cells from a completely unrelated strain of mouse (strain b) are infected with the same strain of influenza and used as targets, the cytotoxic T cells from the strain a mouse are unable to kill the infected strain b target cells (see Figure 23-20b, 1 vs. 4). It is therefore not sufficient that the antigen (an influenza-derived protein) is present; recognition by cytotoxic T cells is *restricted* by mouse strain-specific elements. Genetic mapping showed that these restricting elements are encoded by genes in the MHC. Thus cytotoxic T cells from one mouse strain immune to influenza will kill influenza-infected target cells from another mouse strain only if the two strains match at the MHC for the relevant MHC molecules. This phenomenon is therefore known as *MHC restriction*.

T Cells with Different Functional Properties Are Guided by Two Distinct Classes of MHC Molecules

The MHC encodes two types of glycoproteins essential for immune recognition, commonly called *class I* and *class II MHC molecules*. The class I and class II MHC products are both involved in presenting antigen to T cells, but they serve two broadly distinct functions. Class I MHC products

EXPERIMENTAL FIGURE 23-20 Chromium (^{51}Cr) release assay allows the direct demonstration of the cytotoxicity and specificity of cytotoxic T cells in a heterogeneous population of cells. (a) A suspension of spleen cells, containing cytotoxic (killer) T cells is prepared from mice that have been exposed to a particular virus (e.g., influenza virus) and have cleared the infection. Target cells obtained from the same strain are infected with the identical virus or left uninfected. After infection, cellular proteins are labeled nonspecifically by incubation of the target-cell suspension with ^{51}Cr . Upon incubation of radiolabeled target cells with the suspension of T cells, killing of target cells results in release of the ^{51}Cr -labeled proteins.

Uninfected target cells are not killed and retain their radioactive contents. Lysis of cells by cytotoxic T cells can therefore be readily detected and quantitated by measuring the radioactivity released into the supernatant. (b) Cytotoxic T lymphocytes (CTLs) harvested from mice that have been infected with virus X can be tested against various target cells to determine the specificity of CTL-mediated killing. CTLs capable of lysing virus X-infected target cells (**1**) cannot kill uninfected cells (**2**) or cells infected with a different virus, Y (**3**). When these CTLs are tested on virus X-infected targets from a strain that carries an altogether different MHC type (b), again no killing is observed (**4**). Cytotoxic T-cell activity is thus virus specific and restricted by the MHC.

mostly serve to alert cytotoxic T cells to the presence of intracellular invaders and allows the cytotoxic T cell to destroy the infected cell; this function goes hand in hand with the cell biological processes that govern the assembly and display of class I MHC products. Class II MHC products are

found on professional antigen-presenting cells: when the class II molecules on such cells present antigen, often acquired from the extracellular environment, to helper T cells, this is mostly interpreted by the immune system as a call to arms and an immediate need for an adaptive immune

response that requires B-cell involvement, cytokine production, and also assistance to cytotoxic T cells. Again, the underlying cell biology that describes expression, assembly, and mode of antigen presentation by class II MHC molecules fits this functional specialization rather neatly, as we shall see below.

A comparison of the genetic maps of the mouse and human MHCs shows the presence of several class I MHC genes and several class II MHC genes, even though their arrangement shows variation between the different species (see Figure 23-19). In addition to the class I and class II MHC molecules, the MHC encodes key components of the antigen-processing and presentation machinery. Finally, the typical vertebrate MHC also encodes key components of the complement cascade. Class I and class II MHC molecules are recognized by different populations of immune system cells and therefore serve different functions.

As should be clear from the experiments outlined in Figure 23-20, cytotoxic T cells are guided in the recognition of their targets by MHC molecules. These T cells mostly use class I MHC molecules as their restriction elements, and also are characterized by the presence of the CD8 glycoprotein marker on their surface. Most, if not all, nucleated cells constitutively express class I MHC molecules and can support replication of viruses. Cytotoxic T cells recognize and kill the infected targets via the expressed class I MHC molecules that display virus-derived antigen.

As mentioned previously, B cells do not undergo final differentiation into antibody-secreting plasma cells without assistance from another subset of T cells, the *helper T cells* (or T helper cells). Helper T cells express on their surface the CD4 glycoprotein marker and use class II MHC molecules as restriction elements. The constitutive expression of class II MHC molecules is confined to so-called *professional* antigen-presenting cells, including B cells, dendritic cells, and macrophages. (Several other cell types, some in epithelia, can be induced to express class II MHC molecules, but we will not discuss these.)

The two major groups of functionally distinct T lymphocytes—cytotoxic T cells and helper T cells—can thus be distinguished based on the unique profile of membrane proteins displayed at their cell surface and by the MHC molecules they use as restriction elements:

- Cytotoxic T cells: CD8 marker; class I MHC restricted
- Helper T cells: CD4 marker; class II MHC restricted

Both CD4 and CD8 belong to the immunoglobulin (Ig) superfamily of proteins, which all include one or more Ig domains. The B-cell and T-cell receptors, polymeric IgA receptor, and many cell-adhesion molecules (Chapter 19) also belong to the Ig superfamily. The molecular basis for the strict correlation between expression of CD8 and utilization of class I MHC molecules or between expression of CD4 and utilization of class II MHC molecules as the restriction element will become evident once the structure and mode of action of MHC molecules has been described.

MHC Molecules Bind Peptide Antigens and Interact with the T-Cell Receptor

Both class I and class II MHC molecules are highly *polymorphic*; that is, many allelic variants exist among individuals of the same species. The vertebrate immune system can respond to these allelic differences, and this ability to recognize allelic MHC variants is the underlying immunological cause for rejection of transplants that involve unrelated, genetically distinct individuals. Yet both classes of MHC molecules also are structurally similar in many respects, as are their interactions with peptides and the T-cell receptor (Figure 23-21).

Class I MHC Molecules Class I MHC molecules belong to the Ig superfamily and consist of two polypeptides. The larger subunit is a type I membrane glycoprotein (see Figure 13-10) encoded by the MHC. The smaller β 2-microglobulin subunit is not encoded by the MHC and corresponds in structure to a free Ig domain. Originally purified from human leukocytes by digestion with papain, which releases the extracellular portion of the class I MHC molecules in intact form, these proteins are now produced by recombinant DNA technology procedures and have become important tools for the detection of antigen-specific T cells.

Implicit in the notion that MHC molecules are the targets of graft rejection is their structural variation, attributable to inherited variation (genetic polymorphism): If a recipient rejects a graft, the recipient's immune system must be capable of distinguishing unique features of the donor MHC molecules present on the graft. In fact, the genes encoded by the MHC are among the most polymorphic currently known, with over 2000 distinct allelic products identified in humans. The class I MHC molecules in humans are encoded by the HLA-A, HLA-B, and HLA-C loci (see Figure 23-19), each displaying extensive allelic variation. In the mouse, the class I MHC molecules are encoded by the H-2K and H-2D loci, each likewise with many known allelic variants. The three-dimensional structure of class I MHC molecules reveals two membrane-proximal Ig-like domains. These domains support an eight-stranded β -pleated sheet topped by two α helices. Jointly the β sheet and the helices create a cleft, closed at both ends, in which a peptide binds (see Figure 23-21a). The mode of peptide binding by a class I MHC molecule requires a peptide of rather fixed length, usually 8 to 10 amino acids, so that the ends of the peptide can be tucked into pockets that accommodate the charged amino and carboxyl groups at the termini. Further, the peptide is anchored into the peptide-binding cleft by means of a small number of amino acid side chains, each of which is accommodated by a pocket in the MHC molecule that neatly fits that particular amino acid residue (Figure 23-22a). On average, two such "specificity pockets" must be filled correctly to allow stable peptide binding. In this manner, a given MHC molecule can accommodate a large number of peptides of diverse sequence, as long as the "anchor" requirements are fulfilled.

The polymorphic residues that distinguish one allelic MHC molecule from another are mostly located in and

around the peptide-binding cleft. These residues therefore determine the architecture of the peptide-binding pocket and hence the specificity of peptide binding. Further, these polymorphic residues affect the surface of the MHC molecule and hence the points of contact with the T-cell receptor. A T-cell receptor designed to interact with one particular class

FIGURE 23-21 Three-dimensional structure of class I and class II MHC molecules. (a) Shown here is the structure of a class I MHC molecule with bound peptide as determined by x-ray crystallography. The portion of a class I MHC molecule that binds peptide consists of a β sheet composed of eight β strands and flanked by two α helices. The peptide-binding cleft is formed entirely from the MHC-encoded large subunit, which associates noncovalently with the small subunit (β 2-microglobulin) encoded elsewhere. (b) Class II MHC molecules are structurally similar to class I molecules, but with several important distinctions. Both the α and β subunits of class II MHC molecules are MHC encoded and contribute to formation of the peptide-binding cleft. The peptide-binding cleft of class II MHC molecules accommodates a wider range of peptide sizes than that of class I molecules. [Part (a) based on D. N. Garboczi, 1996, *Nature* **384**:134. Part (b) based on J. Hennecke et al., 2000, *EMBO J.* **19**:5611.]

I MHC allele will therefore, as a rule, not interact with unrelated MHC molecules because of their different surface architectures (Figure 23-22b); this is the molecular basis of MHC restriction. The CD8 marker functions as a co-receptor, binding to conserved portions of the class I MHC molecules. The presence of CD8 thus “sets” the restriction specificity of any mature T cell that bears it.

Class II MHC Molecules The two subunits (α and β) of class II MHC molecules are both type I membrane glycoproteins and belong to the Ig superfamily. The typical mammalian MHC contains several loci that encode class II MHC molecules (see Figure 23-19). Like the large subunit of class I molecules, both the α and β subunits of class II molecules show genetic polymorphism.

The basic three-dimensional design of class II MHC molecules resembles that of class I MHC molecules: two membrane-proximal Ig-like domains support a peptide-binding portion composed of an eight-stranded β sheet and two α helices (see Figure 23-21b). For class II MHC molecules, the α and β subunits contribute equally to the construction of the peptide-binding cleft. This cleft is open at both ends and thus supports the binding of longer peptides that protrude from it. The mode of peptide binding involves pockets that accommodate specific peptide side chains, as well as contacts between side chains of the MHC molecule with main-chain atoms of the bound peptide. As for class I MHC, class II MHC polymorphisms mainly affect residues in and around the peptide-binding cleft, so that the peptide-binding specificity will usually differ among different allelic products.

A T-cell receptor that interacts with a particular class II MHC molecule will not, as a rule, interact with a different allelic molecule, not only because of the difference in the peptide-binding specificity of the allelic molecules, but also because of the polymorphisms that affect the contact residues with the T-cell receptor; as for class I MHC, this is the basis for class II MHC restricted recognition of antigen. As discussed below, class II MHC molecules evolved to present peptides generated predominantly in endosomes and lysosomes. The interactions between a peptide and class II MHC

FIGURE 23-22 Peptide binding and MHC restriction. (a) Peptides that bind to class I molecules are on average 8–10 residues in length, require proper accommodation of the termini, and include two or three residues that are conserved (anchor residues). Positions in class I molecules that distinguish one allele from another (polymorphic residues) occur in and around the peptide-binding cleft. The polymorphic residues in the MHC affect both the specificity of peptide binding and the interactions with T-cell receptors. Successful “recognition” of a peptide antigen–MHC complex by a T-cell receptor requires a good fit among the receptor, peptide, and MHC molecule. (b) Steric clash and a lack of complementarity between anchor residues and the MHC molecule prevent proper binding. T-cell receptors are thus restricted to specific peptide–MHC products.

molecule take place in these organelles, and class II MHC molecules are targeted specifically to those locations after their synthesis in the endoplasmic reticulum.

This targeting is accomplished by means of a chaperone called the invariant chain, a type II membrane glycoprotein (see Figure 13-10). The invariant chain (Ii) plays a key role

in the early stages of class II MHC biosynthesis by forming a trimeric structure onto which the class II MHC $\alpha\beta$ heterodimers assemble. The final assembly product thus consists of nine polypeptides: $(\alpha\beta Ii)_3$. The interaction between Ii and the $\alpha\beta$ heterodimer involves a stretch of Ii called the CLIP segment, which occupies the class II MHC peptide-binding cleft. Once the $(\alpha\beta Ii)_3$ complex is assembled, the complex enters the secretory pathway and is diverted to endosomes and lysosomes at the *trans*-Golgi network (see Figure 14-1). The signals responsible for this diversion are carried by the Ii cytoplasmic tail and do not obviously conform to the endosomal targeting or retrieval signals commonly found on lysosomal membrane proteins. Some of the $(\alpha\beta Ii)_3$ complexes are directed straight to the cell surface from which they may be internalized, but the vast majority end up in late endosomes.

As we saw for class I MHC molecules and their CD8 co-receptor, the CD4 co-receptor recognizes conserved features on class II MHC molecules. Any mature T cell that bears the CD4 co-receptor uses class II MHC molecules for antigen recognition.

Antigen Presentation Is the Process by Which Protein Fragments Are Complexed with MHC Products and Posted to the Cell Surface

The process by which foreign materials enter the immune system is the key step that determines the eventual outcome of a response. A successful adaptive immune response, which includes the production of antibodies and the generation of helper and cytotoxic T cells, cannot unfold without the involvement of professional antigen-presenting cells. Professional antigen-presenting cells include dendritic cells and macrophages, both bone marrow-derived, and B cells. It is these cells that acquire antigen, process it, and then display it in a form that can be recognized by T cells. The pathway by which antigen is converted into a form suitable for T-cell recognition is referred to as *antigen processing and presentation*.

The class I MHC pathway focuses predominantly on presentation of proteins synthesized by the cell itself, and the class II MHC pathway is centered on materials acquired from outside the antigen-presenting cell. Recall that all nucleated cells express class I MHC products, or can be induced to do so; this makes sense in view of the fact that a nucleated cell is capable of synthesizing nucleic acids as well as protein, and can thus in principle sustain replication of a viral pathogen. Its ability to alert the immune system to the presence of an intracellular invader is inextricably linked to class I MHC-restricted antigen presentation. The distinction between presentation of materials synthesized by an antigen-presenting cell itself, and processing and presentation of antigen acquired from outside the cell, is by no means absolute. Together, the class I and class II pathways of antigen processing and presentation sample all of the compartments that need to be surveyed for the presence of pathogens.

Antigen processing and presentation in both the class I and II pathways may be divided into six discrete steps that are useful in comparing the two pathways: (1) acquisition of antigen, (2) tagging the antigen for destruction, (3) proteolysis, (4) delivery of peptides to MHC molecules, (5) binding of peptide to a MHC molecule, and (6) display of the peptide-loaded MHC molecule on the cell surface. In the next two sections, we describe the molecular details of each pathway.

Class I MHC Pathway Presents Cytosolic Antigens

Figure 23-23 summarizes the six steps in the class I MHC pathway using a virus-infected cell as an example. The following discussion describes the events that occur during each step:

1 Acquisition of Antigen: In the case of a virus infection, acquisition of antigen is usually synonymous with the infected state. Viruses rely on host protein synthesis to generate the building blocks for new virions. This includes the synthesis of viral cytosolic proteins as well as membrane proteins. Protein synthesis, unlike DNA replication, is an error-prone process, with a fraction of newly initiated polypeptide chains being terminated prematurely or suffering from other errors (misincorporation of amino acids, frame-shifts, improper or delayed folding). These mistakes in protein synthesis affect both the host cell's own proteins and those specified by viral genomes. Such error-containing proteins must be rapidly removed so as not to clog up the cytoplasm, engage partner proteins in nonproductive interactions, or even act as dominant negative versions of a

FIGURE 23-23 Class I MHC pathway of antigen processing and presentation. Step **1**: Acquisition of antigen is synonymous with the production of proteins with errors (premature termination, misincorporation). Step **2**: Misfolded proteins are targeted for degradation through conjugation with ubiquitin. Step **3**: Proteolysis is carried out by the proteasome. In cells exposed to interferon γ , the catalytically active β subunits of the proteasome are replaced by interferon-induced

immune-specific β subunits. Step **4**: Peptides are delivered to the interior of the endoplasmic reticulum (ER) via the dimeric TAP peptide transporter. Step **5**: Peptide is loaded onto newly made class I MHC molecules within the peptide-loading complex. Step **6**: The fully assembled class I MHC-peptide complex is transported to the cell surface via the secretory pathway. See text for details.

protein. The rate of cytosolic proteolysis must be matched to the rate at which mistakes in protein synthesis and folding occur. These proteins are an important source of antigen peptides destined for presentation by class I MHC molecules. With the exception of cross-presentation (discussed below), the class I MHC pathway results in the formation of peptide-MHC complexes in which the peptides are derived from proteins synthesized by the class I MHC-bearing cell itself.

2 Targeting the Antigen for Destruction: For the most part, the ubiquitin conjugation system is responsible for targeting a protein for destruction (see Chapter 3, p. 87). Ubiquitin conjugation is a covalent modification that is tightly regulated.

3 Proteolysis: Ubiquitin-conjugated proteins are destroyed by proteasomal proteolysis. The proteasome is a highly processive protease that engages its substrates and, without the release of intermediates, yields final digestion products, peptides in the size range of 3–20 amino acids (see Figure 3-29). During the course of an inflammatory response and in response to interferon γ , the three catalytically active β subunits ($\beta 1$, $\beta 2$, $\beta 5$) of the proteasome can be replaced by three immune-specific subunits: $\beta 1i$, $\beta 2i$, and $\beta 5i$. The $\beta 1i$, $\beta 2i$, and $\beta 5i$ subunits are encoded in the MHC locus. The net result of this replacement is the generation of the *immunoproteasome*, the output of which is matched to the requirements for peptide binding by class I MHC molecules. The immunoproteasome adjusts the average length of the peptides produced as well as the sites at which cleavage occurs. Given the central role of the proteasome in the generation of peptides presented by class I MHC molecules, proteasome inhibitors interfere potently with antigen processing via the class I MHC pathway.

4 Delivery of Peptides to Class I Molecules: Protein synthesis, ubiquitin conjugation, and proteasomal proteolysis all occur in the cytoplasm, whereas peptide binding by class I MHC molecules occurs in the lumen of the endoplasmic reticulum (ER). Thus peptides must cross the ER membrane to gain access to class I molecules, a process mediated by the heterodimeric TAP complex, a member of the **ABC superfamily** of ATP-powered pumps (see Figure 11-15). The TAP complex binds peptides on the cytoplasmic face and, in a cycle that includes ATP binding and hydrolysis, peptides are translocated into the ER. The specificity of the TAP complex is such that it can transport only a subset of all cytosolic peptides, primarily those in the length range of 5–10 amino acids. The mouse TAP complex shows a pronounced preference for peptides that terminate in leucine, valine, isoleucine, or methionine residues, which match the binding preference of the class I MHC molecules served by the TAP complex. The genes encoding the TAP1 and TAP2 subunits composing the TAP complex are located in the MHC locus.

5 Binding of Peptides to Class I Molecules: Within the ER, newly synthesized class I MHC molecules are part of a

multi-protein complex referred to as the peptide-loading complex. This complex includes two chaperones (calnexin and calreticulin) and the oxidoreductase Erp57. Another chaperone (tapasin) interacts with both the TAP complex and the class I MHC molecule about to receive peptide. The physical proximity of TAP and the class I MHC molecule is maintained by tapasin. Once peptide loading has occurred, a conformational change releases the loaded class I MHC molecule from the peptide-loading complex. This arrangement effectively ensures that only peptide-loaded molecules are displayed at the cell surface.

6 Display of Class I MHC–Peptide Complexes at the Cell Surface: Once peptide loading is complete, the class I MHC–peptide complex is released from the peptide-loading complex and enters the constitutive secretory pathway (see Figure 14-1). Transfer from the Golgi to the cell surface is rapid and completes the biosynthetic pathway of a class I MHC–peptide complex.

The entire sequence of events in the class I pathway occurs constitutively in all nucleated cells, which express class I MHC molecules and the other required proteins or can be induced to do so. In the absence of a virus infection, protein synthesis and proteolysis continuously generate a stream of peptides that are loaded onto class I MHC molecules. Healthy, normal cells therefore display on their surface a representative selection of peptides derived from host proteins. There may be several thousand distinct MHC–peptide combinations displayed at the surface of a typical nucleated cell. Developing T cells in the thymus calibrate their antigen-specific receptors on these sets of MHC–peptide complexes, and learn to recognize self-MHC products as the “restriction elements” on which they must henceforth rely for antigen recognition. At the same time, the display of self-peptides by self-MHC molecules in the thymus enables the developing T cell to learn which peptide-MHC combinations are self-derived and must therefore be ignored to avoid a self-destructive autoimmune reaction. T-cell development is thus driven by self-MHC molecules loaded with self-peptides, a “template” on which a useful repertoire of T cells can be molded. Simply put, any T cell that bears a receptor that too strongly reacts with self peptide MHC complexes is potentially dangerous when it escapes from the thymus, and must be eliminated. This is an aspect of T-cell development that will be discussed below.

It is not until a virus makes its appearance that virus-derived peptides begin to make a contribution to the display of peptide-MHC complexes. The overall efficiency of this pathway is such that approximately 4000 molecules of a given protein must be destroyed to generate a single MHC–peptide complex carrying a peptide from that particular polypeptide.

An unusual mode of antigen presentation that is nonetheless crucial in the development of cytotoxic T cells is *cross-presentation*. This term refers to the acquisition by dendritic cells of apoptotic cell remnants, immune complexes, and possibly other forms of antigen by phagocytosis. By a pathway that has yet to be fully understood, these

materials escape from phagosomal/endosomal compartments into the cytosol, where they are then handled according to the steps described above. Only dendritic cells are capable of cross-presentation, and so allow the loading of class I MHC molecules complexed with peptides that derive from cells other than the antigen-presenting cell itself. Autophagy (see Chapter 14) is likely to play a role in this process.

Class II MHC Pathway Presents Antigens Delivered to the Endocytic Pathway

Although class I MHC and class II MHC molecules show a striking structural resemblance, the manner in which the two classes acquire peptide and their function in immune recognition differs greatly. Whereas the primary function of class I MHC molecules is to guide CD8-bearing cytotoxic T cells to their target cells, class II MHC molecules serve to guide CD4-bearing helper T cells to the cells with which they interact, primarily professional antigen-presenting cells. Activated CD4 T cells provide protection not only via the assistance provided to B cells in producing antibodies, but also by the complex sets of cytokines they produce, which activate phagocytic cells to clear pathogens, or help set up an inflammatory response.

As noted previously, class II MHC molecules are expressed primarily by professional antigen-presenting cells: dendritic cells and macrophages, which are phagocytic, and B cells, which are not. Hence, the class II MHC pathway of antigen processing and presentation generally occurs only in these cells. The steps in this pathway are depicted in Figure 23-24 and described below.

1 Acquisition of Antigen: In the class II MHC pathway, antigen is acquired by pinocytosis, phagocytosis, or receptor-mediated endocytosis. Pinocytosis, which is rather nonspecific, involves the delivery, by a process of membrane invagination and fission, of a volume of extracellular fluid and the molecules dissolved therein. **Phagocytosis**, the ingestion of particulate materials, such as bacteria, viruses, and remnants of dead cells, involves extensive remodeling of the actin-based cytoskeleton to accommodate the incoming particle. Although phagocytosis may be initiated by specific receptor-ligand interactions, these are not always required: Even latex particles can be ingested very efficiently by macrophages. In the process of opsonization, pathogens decorated by antibodies and certain complement components are targeted to macrophages and dendritic cells, recognized by cell-surface receptors for complement components or receptors for the Fc portion of immunoglobulins, and then phagocytosed (Figure 23-25). Macrophages and dendritic cells also express several types of less selective receptors (e.g., C-type lectins, Toll-like receptors, scavenger receptors) that recognize molecular patterns on nonparticulate antigens; the bound antigen is internalized by **receptor-mediated endocytosis**. B cells, which are not phagocytic, also can acquire antigen by receptor-mediated endocytosis using their antigen-specific B-cell receptors

(surface immunoglobulin) (Figure 23-26). Finally, cytosolic antigens may enter the class II MHC pathway via autophagy (see Figure 14-35). After formation of the autophagic cup, an autophagic vesicle is formed. These vesicles are of a size that can accommodate damaged organelles, and sizable quantities of cytoplasm may be encapsulated in the process. The resulting autophagosomes are destined to fuse with lysosomes, where the contents of the autophagosome then become available for digestion by lysosomal proteases.

2 Targeting Antigen for Destruction: Proteolysis is required to convert intact protein antigen into peptides of a size suitable for binding to class II MHC molecules. Protein antigens are targeted for degradation by progressive unfolding, brought about by the drop in pH as proteins progress along the endocytic pathway. The pH of the extracellular environment is around pH 7.2, and that in early endosomes is between pH 6.5 and 5.5; in late endosomes and lysosomes the pH may drop to pH 4.5. ATP-powered V-class proton pumps in the endosomal and lysosomal membranes are responsible for this acidification (see Figure 11-9). Proteins that are stable at neutral pH tend to unfold when they are exposed to extremes of pH, through rupture of hydrogen bonds and destabilization of salt bridges. Further, the environment in the endosomal/lysosomal compartments is reducing, with lysosomes attaining a concentration of reducing equivalents in the millimolar range. Reduction of disulfide bonds that stabilize many extracellular proteins is the reversal of a covalent modification, catalyzed also by a thioreductase inducible by exposure to IFN- γ . The combined action of low pH and reducing environment prepares the antigens for proteolysis.

3 Proteolysis: Degradation of proteins in the class II MHC pathway is carried out by a large set of lysosomal proteases, collectively referred to as cathepsins, which are either cysteine or aspartyl proteases. Other proteases, such as asparagine-specific endoprotease, also may contribute to proteolysis. A wide range of peptide fragments is produced, including some that can bind to class II MHC molecules. The lysosomal proteases operate optimally at the acidic pH within lysosomes. Consequently, agents that inhibit the activity of V-class proton pumps interfere with antigen processing, as do inhibitors of lysosomal proteases.

4 Encounter of Peptides with Class II Molecules: Recall that most class II MHC molecules synthesized in the endoplasmic reticulum are directed to late endosomes. Because the peptides generated by proteolysis reside in the same topological space as the class II MHC molecules themselves, the delivery of peptide to class II MHC molecules does not require traversal of a membrane. The sole requirement, therefore, is to allow peptides and class II MHC molecules to meet. This is accomplished in the course of biosynthesis by a sorting step that is dependent on the invariant chain (Ii) and ensures delivery of the class II ($\alpha\beta$ Ii)₃ complex to endosomal compartments.

5 Binding of Peptides to Class II Molecules: The ($\alpha\beta$ Ii)₃ complex delivered to endosomal compartments is incapable

FIGURE 23-24 Class II MHC pathway of antigen processing and presentation. Step 1: Particulate antigens are acquired by phagocytosis, and nonparticulate antigens by pinocytosis or endocytosis. Step 2: Exposure of antigen to the low pH and reducing environment of endosomes and lysosomes prepares the antigen for proteolysis. Step 3: The antigen is broken down by various proteases in endosomal and lysosomal compartments. Step 4: Class II MHC molecules, assembled in the ER from their subunits, are delivered to endosomal/

lysosomal compartments by means of signals contained in the associated invariant (Ii) chain. This delivery targets late endosomes, lysosomes, and early endosomes, ensuring that class II MHC molecules are exposed to the products of proteolytic breakdown of antigen along the entire endocytic pathway. Step 5: Peptide loading is accomplished with the assistance of DM, a class II MHC-like chaperone protein. Step 6: Display of peptide-loaded class II MHC molecules at the cell surface. See text for details.

of binding peptide because the peptide-binding cleft in the class II molecule is occupied by Ii. For the same reason, newly assembled class II ($\alpha\beta\text{Ii}$)₃ complexes do not compete for class I MHC-destined peptides delivered to the ER via TAP: their peptide binding site is already occupied by Ii. Recall that the ER is the site where both class I and class II MHC molecules assemble. The presence of Ii in the nascent class II MHC complex ensures that only class I MHC

molecules bind peptide in the ER. The same proteases that act on internalized antigens and degrade them into peptides act also on the ($\alpha\beta\text{Ii}$)₃ complex, resulting in removal of Ii with the exception of a small portion called the CLIP segment. Because it is firmly lodged in the class II MHC peptide-binding cleft, CLIP is resistant to proteolytic attack. The class II MHC molecules themselves are also resistant to unfolding and proteolytic attack under the conditions that

FIGURE 23-25 Presentation of opsonized antigen by phagocytic cells. By means of Fc receptors such as FcγR displayed on their cell surface, specialized phagocytic cells such as macrophages or dendritic cells can bind and ingest pathogens that have been decorated with antibodies (opsonization). After digestion of the phagocytosed particle (e.g., immune complex, bacterium, virus), some of the peptides produced, including fragments of the pathogen (orange), are loaded onto class II MHC molecules (green). Class II MHC–peptide complexes displayed at the surface allow activation of T cells specific for these MHC–peptide combinations. Lipid antigens are delivered to the class I MHC–like molecule CD1 (pink), whose binding site is specialized to accommodate lipids. Certain pathogen-derived peptides (purple) may be delivered to class I MHC products (blue) by means of cross-presentation. The mechanisms that underlie cross-presentation remain to be clarified.

FIGURE 23-26 Antigen presentation by B cells. B cells bind antigen, even if present at low concentration, to their B-cell receptors, or surface Ig. The immune complex that results is internalized and then delivered to endosomal/lysosomal compartments, where it is destroyed. Peptides liberated from the immune complex, including fragments of the protein antigen, are displayed as class II MHC–peptide complexes at the cell surface. CD4 T cells specific for the displayed complex can now provide help to the B cell. This help is MHC restricted and antigen specific.

prevail in the endocytic pathway. The CLIP segment is removed through interaction of the αβCLIP complex with a chaperone, DM. The newly vacated peptide-binding cleft of the class II MHC molecule may now bind peptides that are abundantly present in the endocytic pathway. Although the DM protein is MHC encoded and structurally very similar to class II molecules, it does not itself bind peptides. However, newly formed class II MHC–peptide complexes are themselves susceptible to further “editing” by DM by dislodging of the peptide already bound, until the class II molecule acquires a peptide that binds so strongly that it cannot be removed by further interactions of the complex with DM. The resulting class II MHC–peptide complexes are extremely stable, with estimated half-lives in excess of 24 hours.

6 Display of Class II MHC–Peptide Complexes at the Cell Surface: The newly generated class II MHC–peptide complexes are localized mostly in late endosomal

compartments, which include multivesicular endosomes (or bodies) (see Figure 14-33). Recruitment of the internal vesicles of the multivesicular bodies to the delimiting membrane expands their surface area: by a process of tubulation along tracks of microtubules, these compartments elongate and ultimately deliver class II MHC-peptide complexes to the surface by membrane fusion. These events are tightly regulated: tubulation and delivery of class II MHC molecules to the surface are enhanced in dendritic cells and macrophages following their activation in response to signals, such as bacterial lipopolysaccharide (LPS), which is detected by their Toll-like receptors.

For professional antigen-presenting cells, the above steps are constitutive—happening all the time—but they can be modulated by exposure to microbial agents and cytokines. In addition to the pathways described here for class I and class II MHC products, there is a category of class I MHC-related molecules, the CD1 proteins, which are specialized in the presentation of lipid antigens. The structure of CD1 molecules resembles that of a class I MHC molecule: a heavy chain in complex with β 2-microglobulin. Many species of bacteria produce lipids of a chemical structure that is not found in their mammalian hosts. These lipids can serve as antigens recognized in host defense when presented by CD1 molecules, where they bind to a lipid-binding pocket that is conceptually similar to that of the peptide-binding pocket of regular MHC molecules. Signals in the cytoplasmic tail of the CD1 heavy chain target these molecules to endolysosomal compartments, where loading with lipid occurs. The CD1-lipid complexes engage a prominent class of T cells, referred to as NKT cells based on their surface characteristics, as well as to $\gamma\delta$ T cells described below. NKT cells fulfill an important role in cytokine production and help initiate and orchestrate adaptive immune responses via their cytokine outputs.

KEY CONCEPTS of Section 23.4

The MHC and Antigen Presentation

- The MHC, discovered as the genetic region responsible for acceptance or rejection of grafts, encodes two major classes of type I membrane glycoproteins, class I and class II MHC molecules. These proteins are highly polymorphic, occurring in many allelic variations in an outbred population (see Figure 23-19).
- The function of MHC products is to bind peptides and display them to antigen-specific receptors on T cells. Class I MHC molecules are found on most nucleated cells, whereas the expression of class II MHC molecules is confined largely to professional antigen-presenting cells such as dendritic cells, macrophages, and B cells.
- The organization and structure of class I and class II MHC molecules is similar and includes a region specialized for binding a wide variety of different peptides (see Figure 23-21).

- Different allelic variants of MHC molecules bind different sets of peptides, because the differences that distinguish one allele from another include residues that define the architecture of the peptide-binding cleft (see Figure 23-22). Allelic residues also include residues contacted by the T-cell receptor for antigen. Thus different allelic variants of an MHC molecule, even if they were to bind the identical peptide, will not usually react with a T-cell receptor designed to interact with only one of the allelic MHC molecules. This phenomenon is called MHC restriction.

- Class I and class II MHC molecules sample different intracellular compartments for peptide: class I molecules sample predominantly cytosolic materials, whereas class II molecules sample extracellular materials internalized by phagocytosis, pinocytosis, or receptor-mediated endocytosis.

- The process by which protein antigens are acquired, processed into peptides, and converted into surface-displayed MHC-peptide complexes is referred to as antigen processing and presentation. This process operates continuously in cells that express the relevant MHC molecules, yet can be modulated in the course of an immune response.

- Antigen processing and presentation can be divided into six discrete steps: (1) acquisition of antigen; (2) targeting the antigen for destruction; (3) proteolysis; (4) encounter of peptides with MHC molecules; (5) binding of peptide to the MHC molecule; and (6) display of the peptide-loaded MHC molecules on the cell surface (see Figures 23-25 and 23-26).

23.5 T Cells, T-Cell Receptors, and T-Cell Development

T lymphocytes recognize antigen through the lens of MHC molecules. The receptors entrusted with this task are structurally related to immunoglobulins. To generate these antigen-specific receptors, T cells rearrange the genes encoding the T-cell receptor (TCR) subunits by mechanisms of somatic recombination essentially identical to those used by B cells to rearrange immunoglobulin genes. The development of T cells is also strictly dependent on successful completion of the somatic gene rearrangements that yield the TCR subunits. We shall describe the subunits that mediate antigen-specific recognition, how they pair up with membrane glycoproteins essential for signal transduction, and how these complexes recognize MHC-peptide combinations.

As pointed out in the preceding section, T cells recognize antigens only together with the polymorphic MHC molecules that happen to be present in that host. In the course of T-cell development, T cells must “learn” the identity of these “self” MHC molecules and receive instructions about which MHC-peptide combinations to ignore, so as to avoid potentially catastrophic reactivity of newly generated T cells with the host’s own tissues (i.e., autoimmunity). We shall describe

how T cells develop, and introduce the major classes of T cells according to their function.

The Structure of the T-Cell Receptor Resembles the F(ab) Portion of an Immunoglobulin

Much as B cells utilize the B-cell receptors to recognize antigens and then transduce signals that lead to their clonal expansion, so T cells use their T-cell receptors. T cells that have been activated through engagement of these antigen-specific receptors proliferate and acquire the capacity to kill antigen-bearing target cells or to secrete cytokines that will assist B cells in their differentiation. The T-cell receptor for antigen recognizes MHC molecules complexed with the appropriate peptides.

The T-cell receptor (Figure 23-27) is composed of two glycoprotein subunits, each of which is encoded by a somatically rearranged gene. The receptors are composed of either an $\alpha\beta$ pair or a $\gamma\delta$ pair. The structure of these subunits shows structural similarity to the F(ab) portion of an immunoglobulin: at the N-terminal end there is a variable domain, followed by a constant-region domain and a transmembrane segment. The cytoplasmic tails of the TCR subunits are too short to allow recruitment of cytosolic factors that assist in signal transduction. Instead, the TCR associates with the CD3 complex, a set of membrane proteins composed of γ , δ , ϵ , and ζ chains. (The TCR γ and δ subunits are not to be confused with the similarly designated subunits of the CD3 complex.) The ϵ chain forms a noncovalent dimer with the γ or the δ chain to yield $\delta\epsilon$ and $\gamma\epsilon$ complexes. The external domain of the CD3 subunits is homologous to immunoglobulin domains, and the cytoplasmic domain in each contains an ITAM domain, through which adapter molecules may be recruited upon phosphorylation of tyrosine residues in the ITAMs. The ζ chain is integrated into the CD3-TCR complex as a disulfide-bonded homodimer, and each ζ chain contains three ITAM motifs.

TCR Genes Are Rearranged in a Manner Similar to Immunoglobulin Genes

Virtually all antigen-specific receptors generated by somatic recombination contain a subunit that is the product of V-D-J recombination (e.g., Ig heavy chain; TCR β chain) and a

FIGURE 23-27 Structure of the T-cell receptor and its co-receptors.

(a) The T-cell receptor (TCR) for antigen is composed of two chains, the α and β subunits, which are produced by V-J and V-D-J recombination, respectively. The $\alpha\beta$ subunits must associate with the CD3 complex (see Figure 23-29) to allow the transduction of signals. The formation of a full TCR $\alpha\beta$ -CD3 complex is required for surface expression. The T-cell receptor further associates with the co-receptors CD8 (light blue) or CD4 (light green), which allow interaction with conserved features of class I MHC and class II MHC molecules, respectively, on antigen-presenting cells. (b) Structure of the T-cell receptor bound to a class II MHC-peptide complex as determined by x-ray crystallography.

[Part (b) based on J. Hennecke, 2000, *EMBO J.* 19:5611.]

subunit produced by V-J recombination (e.g., Ig light chain; TCR α chain). The mechanism of V-D-J and V-J recombination for the TCR loci is essentially identical to that described for immunoglobulin genes, and requires all the component proteins composing the nonhomologous end-joining machinery: RAG-1, RAG-2, Ku70, Ku80, DNA-PK catalytic subunit, XRCC4, DNA ligase IV, and Artemis. There is an absolute requirement for the recombination signal sequences (RSSs), and recombination obeys the 12/23-bp spacer rule (Figure 23-28).

A number of noteworthy features characterize the organization and rearrangement of the TCR loci. First, the organization of the recombination signals is such that D-to-D rearrangements are allowed. Second, the enzyme terminal deoxynucleotidyltransferase (TdT) is active at the time the TCR genes rearrange, and therefore N nucleotides can be present in all rearranged TCR genes. Third, in the human and mouse, the TCR δ locus is embedded within the TCR α locus. This organization results in complete excision of the

FIGURE 23-28 Organization and recombination of TCR loci. The organization of TCR loci is in principle similar to that of immunoglobulin loci (see Figure 23-14). *Left:* The TCR β -chain locus includes a cluster of V segments, a cluster of D segments, and several J segments, downstream of which are two constant regions. The arrangement of

the recombination signals is such that not only is D-J joining allowed, but also V-DJ joining. Direct V-J joining in the TCR β locus is not observed. *Right:* The TCR α -chain locus is composed of a cluster of V segments and a large number of J segments. SS = exon encoding signal sequence; Enh = enhancer.

interposed δ locus when TCR α rearrangement occurs, and so a choice of the TCR α locus for rearrangement precludes utilization of the δ locus, now lost by deletion. T cells that express the $\alpha\beta$ receptor and those that express the $\gamma\delta$ receptor are considered separate lineages with distinct functions. Among the T cells expressing $\gamma\delta$ receptors are some capable of recognizing the CD1 molecule, which is specialized in the presentation of lipid antigens. The $\gamma\delta$ T cells are programmed to home in on distinct anatomical sites (e.g., the epithelium lining the genital tract, the skin) and likely play a role in host defense against pathogens commonly found at these sites.

Deficiencies in the key components of the recombination apparatus, such as the RAG recombinases, preclude rearrangement of TCR genes. As we have seen for B cells, and as will be described below for T cells, development of lymphocytes is strictly dependent on the rearrangement of the antigen-receptor genes. A RAG deficiency thus prevents both B- and T-cell development.

T-Cell Receptors Are Very Diverse, with Many of Their Variable Residues Encoded in the Junctions Between V, D, and J Gene Segments

The diversity created by somatic rearrangement of TCR genes is enormous, estimated to exceed 10^{10} unique receptors. Combinatorial usage of different V, D, and J gene segments makes an important contribution, as do the mechanisms of junctional imprecision and N-nucleotide addition already discussed for immunoglobulin gene rearrangements. The net result is a degree of variability in the V regions that matches that of the CDR3s of immunoglobulins (see Figure 23-12). Indeed, each of the TCR's variable regions includes three CDRs, equivalent to those in the BCR. Unlike immunoglobulin genes, however, the TCR genes do not undergo somatic hypermutation. Therefore T-cell receptors exhibit nothing equivalent to the affinity maturation of antibodies during the course of an immune response, nor is there the option of class-switch recombination or the use of alternative polyadenylation sites to create soluble and membrane-bound versions of the antigen-specific receptors.

The crystal structures of a number of T-cell receptors bound to class I MHC-peptide or class II MHC-peptide complexes have been solved. These structures show variability in how the T-cell receptor docks with the MHC-peptide complex, but the most extensive contacts in the somatically diversified CDR3 region are made with the central peptide portion of the complex, with the germ-line-encoded CDR1 and CDR2 contacting the α helices of the MHC molecules. Many of the T-cell receptors for which a structure has been solved sit down diagonally across the peptide-binding portion of the MHC-peptide complex. As a result, the T-cell receptor makes extensive contacts with the peptide cargo as well as with the α helices of the MHC molecule to which it binds. The positions at which allelic MHC molecules differ from one another frequently involve residues that directly contact the T-cell receptor, thus precluding tight binding of the "wrong" allele.

Amino acid differences that distinguish one MHC allele from another also affect the architecture of the peptide-binding cleft. Even if the MHC residues that interact directly with the T-cell receptor were shared by two MHC allelic molecules, their peptide-binding specificity is likely to differ because of amino acid differences in the peptide-binding cleft. Consequently, the TCR contact residues provided by bound peptide and essential for stable interaction with a T-cell receptor would be absent from the "wrong" MHC-peptide combination. A productive interaction with the T-cell receptor is then unlikely to occur.

Signaling via Antigen-Specific Receptors Triggers Proliferation and Differentiation of T and B Cells

Both B-cell and T-cell receptors for antigen transduce signals by means of proteins associated with the antigen-specific portions of the receptor (i.e., Ig heavy and light chains for the BCR; α and β chains for the TCR). The cytosolic portions of the antigen-specific receptors themselves are very short, do not protrude much beyond the cytosolic leaflet of the plasma membrane, and are incapable of recruitment of downstream signaling molecules. Instead, as discussed previously, the antigen-specific receptors on T and B cells associate with auxiliary subunits that contain ITAMs (immunoreceptor tyrosine-based activation motifs). Engagement of antigen-specific receptors by ligand initiates a series of receptor-proximal events: kinase activation, modification of ITAMs, and subsequent recruitment of adapter molecules that serve as scaffolds for recruitment of yet other downstream signaling molecules.

As outlined in Figure 23-29, engagement of antigen-specific receptors activates Src-family tyrosine kinases (e.g., Lck in CD4 T cells; Lyn and Fyn in B cells). These kinases are found in close proximity to or physically associated with the antigen receptor. The active Src kinases phosphorylate the ITAMs in the antigen receptors' auxiliary subunits. In their phosphorylated forms, these ITAMs recruit and activate non-Src-family tyrosine kinases (ZAP-70 in T cells, Syk in B cells) as well as other adapter molecules. Such recruitment and activation involves phosphoinositide-specific phospholipase C_γ and PI-3 kinases. Subsequent downstream events parallel those discussed in Chapter 16 for signaling from receptor tyrosine kinases. Antigen-specific receptors on B and T cells are perhaps best characterized as "modular" receptor tyrosine kinases, with the ligand-recognition units and kinase domains carried by separate molecules. Ultimately, signaling via antigen-specific receptors initiates transcription programs that determine the fate of the activated lymphocyte: proliferation and differentiation.

T cells depend critically on the cytokine interleukin 2 (IL-2) for clonal expansion. Following antigen stimulation of a T cell, one of the first genes to be turned on is that for IL-2. The T cell responds to its own initial burst of IL-2 and proceeds to make more IL-2, an example of autocrine stimulation and part of a positive feedback loop. An important transcription factor required for the induction of IL-2 synthesis is the NF-AT protein

FIGURE 23-29 Signal transduction from the T-cell receptor (TCR) and B-cell receptor (BCR). The signal-transduction pathways used by the antigen-specific receptors of T cells (*left*) and B cells (*right*) are conceptually similar. The initial stages are depicted in this figure;

downstream signaling events lead to changes in gene expression that result in proliferation and differentiation of the antigen-stimulated lymphocytes. See text for further discussion.

(nuclear factor of activated T cells). This protein is sequestered in the cytoplasm in phosphorylated form and cannot enter the nucleus unless it is dephosphorylated first. The phosphatase responsible is calcineurin, a Ca^{2+} -activated enzyme. The initial rise in cytosolic Ca^{2+} leading to activation of calcineurin results from mobilization of ER-resident Ca^{2+} stores triggered by hydrolysis of PIP_2 and the concomitant generation of IP_3 (see Figure 15-36, steps 2–4).

The immunosuppressant drug cyclosporine inhibits calcineurin activity through formation of a cyclosporine-cyclophilin complex, which binds and inhibits calcineurin. If dephosphorylation of NF-AT is suppressed, NF-AT cannot enter the nucleus and participate in the up-regulation of transcription of the IL-2 gene. This precludes expansion of antigen-stimulated T cells and so leads to immunosuppression, arguably the single most important intervention that contributes to successful organ transplantation. Although the success of transplantation varies with the organ used, the availability of strong immunosuppressants such as cyclosporine has expanded enormously the possibilities of clinical transplantation. ■

T Cells Capable of Recognizing MHC Molecules Develop Through a Process of Positive and Negative Selection

The rearrangement of the gene segments that are assembled into a functional T-cell receptor is a stochastic event, completed on the part of the T cell without any prior knowledge of the MHC molecules with which these T-cell receptors must ultimately interact. Similar to somatic recombination of Ig heavy-chain loci in B cells, the first TCR gene segments to rearrange are the $\text{TCR}\beta$ D and J elements, followed by joining of a V segment to the newly recombined DJ. At this stage of T-cell development, productive rearrangement allows the synthesis of the $\text{TCR}\beta$ chain, which is incorporated into the pre-TCR through association with the pre-T α subunit. This pre-TCR fulfills a function strictly analogous to that of the pre-BCR in B-cell development: it tells the T cell that it has successfully completed a productive rearrangement, with no need for further rearrangements on the opposing allele. It allows expansion of pre-T cells that successfully underwent rearrangement, and it imposes allelic exclusion to ensure that, as a rule, a single functional $\text{TCR}\beta$ subunit is generated for a given T cell and its descendants. RAG expression next subsides, and after the ensuing expansion phase of pre-T cells is complete, RAG expression is re-initiated to allow rearrangement of the $\text{TCR}\alpha$ locus, ultimately leading to the generation of T cells with a fully assembled $\text{TCR}\alpha\beta$ receptor. Figure 23-30 illustrates the analogous steps in the development of T and B cells.

How is the newly emerging repertoire of T cells shaped so that a productive interaction with self-MHC molecules can occur? The random nature of the gene rearrangement process and the enormous variability engendered as a conse-

quence produces a set of T-cell receptors, the vast majority of which cannot interact productively with the host MHC products. Recall that antigen processing and presentation are constitutive processes, and that in the thymus, where these selection events take place, all self-MHC molecules are necessarily occupied with peptides derived from self-proteins. These combinations of self-peptides complexed to class I and class II MHC molecules constitute the template on which the initial set of T-cell receptors must be calibrated.

T cells born with receptors that cannot engage self-MHC are useless. Such T cells will fail to perceive survival signals via the newly generated T-cell receptors and die. At the other extreme are T cells endowed with receptors that show a perfect fit for self-MHC complexed with a particular self-peptide. These T cells, if allowed to leave the thymus and take up residence in peripheral lymphoid organs, would be by definition self-reactive and could cause autoimmunity. If the number of such self-peptide MHC combinations surpasses a threshold sufficient to allow triggering of the T-cell receptor, then these T cells are instructed to die in the thymus by apoptosis, the ultimate fate of the vast majority of cells that enter and expand in the thymus. This is called negative selection and serves to purge the T-cell repertoire of overtly self-reactive T cells. Any T cell equipped with a receptor that perceives signals sufficiently strong to allow survival, but below the threshold that would impel the T cell to initiate apoptosis, receives survival signals and is positively selected. The heterogeneity of peptide-MHC complexes displayed on the surface of T cells undergoing selection makes it highly probable that the T-cell receptor interprets signals not only in a qualitative (strength, duration) manner but also in additive fashion: The summation of binding energies of the different MHC-self-peptide combinations on display helps determine the outcome of selection. This is called the *avidity model of T-cell selection*.

T cells are killed off by apoptosis only if the appropriate self-antigen is represented adequately in the thymus as MHC-peptide complexes. Proteins that are expressed in tissue-specific fashion, such as insulin in the β cells of the pancreas or the components of the myelin sheath in the nervous system, obviously do not fit this category. However, a factor called AIRE (autoimmune regulator) allows expression in a subset of epithelial cells of such tissue-specific antigens. How AIRE accomplishes this is not known, but it is widely suspected of directly regulating the transcription of the relevant genes in the thymus and at select sites in secondary lymphoid organs. Defects in AIRE lead to a failure to express these tissue-specific antigens in the thymus. In individuals who do not express AIRE, developing T cells fail to receive the full set of instructions in the thymus that lead to elimination of potentially self-reactive T cells. As a consequence, these individuals show a bewildering array of autoimmune responses, causing widespread tissue damage and disease.

TCR rearrangement occurs coincident with the gradual acquisition of the co-receptors CD4 and CD8. A key intermediate in T-cell development is a thymocyte that expresses CD4 and CD8, as well as a functional TCR-CD3 complex.

FIGURE 23-30 Comparison of T-cell and B-cell development.

Cell fate decisions are executed by receptors composed of either the newly rearranged μ chain (pre-BCR) or the newly rearranged β chain (pre-TCR). The pre-B- and pre-T-cell receptors serve similar functions: expansion of cells that successfully underwent rearrangement and allelic exclusion. This phase of lymphocyte development does not require antigen-specific recognition. Both the pre-BCR and pre-TCR include subunits unique to each receptor and absent from the antigen-specific receptors found on mature lymphocytes: VpreB and

$\lambda 5$ (orange, green) for the pre-BCR; pre-T α (blue) for the pre-TCR. Upon completion of the expansion phase, expression begins of the gene encoding the remaining subunit of the antigen-specific receptor: Ig light chain (light blue) for the BCR; TCR α chain (light red) for the TCR. Lymphocyte development and differentiation occur at distinct anatomical sites, and only fully assembled antigen-specific receptors (BCR, TCR) recognize antigen. Mature lymphocytes are strictly dependent on antigen recognition for their activation.

These cells are called double positive (CD4CD8⁺) cells and are found only as developmental intermediates in the thymus. The choice of which co-receptor (CD4 or CD8) to express determines whether a T cell will recognize class I or class II MHC molecules. How a newborn CD4CD8⁺ cell is instructed to become a CD8 (class I MHC restricted) T cell or CD4 (class II MHC restricted) T cell is not entirely settled.

T Cells Require Two Types of Signal for Full Activation

All T cells require a signal via their antigen-specific receptor, the TCR, for activation, but this is not sufficient: the T cell also needs co-stimulatory signals. To perceive co-stimulatory signals, T cells carry on their surface several different receptors, of which the CD28 molecule is the best-known example. CD28 interacts with CD80 and CD86, two surface glycoproteins on the antigen-presenting cells with which the T cell interacts.

Expression of CD80 and CD86 is up-regulated when these antigen-presenting cells have themselves received the proper stimulatory signals, for example, by engagement of their Toll-like receptors (TLRs). The signals delivered via CD28 synergize with signals that emanate from the engaged T-cell receptor, all of which are required for full activation (Figure 23-31).

T cells, once activated, also express receptors that provide an attenuating or inhibitory signal upon recognition of these very same co-stimulatory molecules. The CTLA4 protein, whose expression on T cells is induced only upon activation, competes with CD28 for binding of CD80 and CD86. Because the affinity of CTLA4 for the CD80 and CD86 proteins is higher than that of CD28, the inhibitory signals provided through CTLA4 will ultimately dominate the stimulatory signals that derive from engagement of CD28. Co-stimulatory molecules can thus be stimulatory or inhibitory and provide an important means of controlling the activation status and duration of a T-cell response.

Cytotoxic T Cells Carry the CD8 Co-receptor and Are Specialized for Killing

As we have seen, cytotoxic T cells, also called cytolytic T lymphocytes (CTLs), generally carry the CD8 glycoprotein marker and are restricted in their recognition by class I MHC molecules. They kill target cells that display the appropriate MHC-peptide combinations and do so with exquisite sensitivity: A single MHC-peptide complex suffices to

FIGURE 23-31 Signals involved in T-cell activation and termination. The two-signal model of T-cell activation involves recognition of an MHC-peptide complex by the T-cell receptor, which constitutes Signal 1 (step 1), along with recognition of co-stimulatory molecules (CD80, CD86) on the surface of the antigen-presenting cell, which constitutes Signal 2 (step 2). If costimulation is not provided, the newly engaged T cell becomes unresponsive (anergic). The provision of both Signal 1 via the T-cell receptor and Signal 2 via engagement of CD80 and CD86 by CD28 allows full activation. Full activation, in turn, leads to increased expression of CTLA4 (step 3). After moving to the T-cell surface, CTLA4 binds CD80 and CD86, leading to inhibition of the T-cell response (step 4). Because the affinity of CTLA4 for CD80 and CD86 is greater than that of the CD28, T-cell activation eventually is terminated.

allow a properly primed CD8 T cell to kill the target cell that bears it.

The mechanism of killing by CTLs involves two classes of proteins that act synergistically, *perforins* and *granzymes* (Figure 23-32). Perforins, which exhibit homology to the terminal components of the complement cascade composing the membrane attack complex, form pores up to 20 nm across in membranes to which they attach. The destruction of an intact permeability barrier, which leads to loss of electrolytes and other small solutes, contributes to cell death. Granzymes are delivered to and are presumed to enter the target cell, likely via the pores generated by perforin. Granzymes are serine proteases that activate effector caspases and so propel the target on a path of programmed cell death (apoptosis). Perforins and granzymes are packaged into cytotoxic granules, stored inside the cytotoxic T cell. Upon binding of the T-cell receptor to antigen, the cytotoxic granules and their contents are released into the cleft formed between the cytotoxic T cell and target cell. How the T cell avoids being killed upon release of granzymes and perforins into this synaptic cleft is still not known. Natural killer cells also exert cytotoxic activity and likewise rely on perforins and granzymes to kill their targets (see Figure 23-5).

T Cells Produce an Array of Cytokines That Provide Signals to Other Immune Cells

Many lymphocytes and nonlymphoid cells in lymphoid tissue produce cytokines. These small secreted proteins instruct lymphocytes what to do by binding to specific receptors on the lymphocyte surface and initiating a transcriptional program that allows the lymphocyte to either proliferate or differentiate into an effector cell ready to exert cytotoxic activity (CD8 T cells), helper activity (CD4 T cells), or antibody-secreting activity (B cells). Cytokines that are produced by or act primarily on leukocytes are called *interleukins*; at least 32 interleukins have been recognized and molecularly characterized. Structurally related interleukins are recognized by cognate receptors with structural similarities, the interleukin-2 receptor being a particularly well-characterized example. Interleukin 2 (IL-2) was identified as T-cell growth factor and is one of the first cytokines produced when T cells

FIGURE 23-32 Perforin- and granzyme-mediated cell killing by cytotoxic T cells. Upon recognition of the target cell (step 1), cytotoxic T cells form tight antigen-specific contacts with target cells. Tight contact results in the formation of a synaptic cleft, into which the contents of cytotoxic granules are released (step 2). The content of these granules includes perforins and granzymes. Perforins form pores in the membranes onto which they adsorb, and granzymes are serine

proteases that enter through the perforin pores (step 3). Perforins are believed to act not only at the surface of the target cells but also at the surface of endosomal compartments of target cells after the perforin molecules have been internalized from the cell surface (step 4). Once in the cytoplasm, the granzymes activate caspases, which initiate programmed cell death (step 5).

are stimulated. IL-2 acts as an autocrine (self-acting) growth factor and drives clonal expansion of activated T cells.

Interleukin 4 (IL-4), which is produced by CD4 T cells specialized in providing help to B cells (discussed below), induces activated B cells to proliferate and to undergo class-switch recombination and somatic hypermutation. Interleukin 7 (IL-7), produced by stromal cells in the bone marrow, is essential for development of T and B cells from committed precursors. Both IL-7 and IL-15 play a role in the maintenance of T cells in the form of *memory cells*, which are antigen-experienced cells that may be called upon when re-exposure to antigen occurs. These memory T cells then rapidly proliferate and deal with the intruder. IL-2, IL-4, IL-7, IL-9, and IL-15 all rely on a common subunit for signal transduction, the common γ_c chain (γ_c) with α (IL-2, IL-15) and β subunits (IL-2, IL-4, IL-7, IL-9, IL-15) providing ligand specificity. Genetic defects in the γ_c result in a near-complete failure in lymphocyte development, illustrating the importance of these cytokines not only during the effector phase of an immune response, but also in the course of lymphocyte development, where IL-7 in particular plays a key role.

The mechanism of signal transduction by cytokine receptors through the JAK/STAT pathway is described in Chapter 16 (see Figure 16-1 for quick review). Among the many genes under the control of the STAT pathway are suppressors of cytokine signaling, or SOCS proteins. These proteins are themselves induced by cytokines, bind to the activated form of JAKs, and target them for proteasomal degradation (see Figure 16-14b).

CD4 T Cells Are Divided into Three Major Classes Based on Their Cytokine Production and Expression of Surface Markers

The major function of CD4 T cells is to provide assistance to B cells and guide their differentiation into plasma cells that secrete high-affinity antibodies. This function, carried out by helper T cells, requires both the production and secretion of cytokines, as well as direct contact between the CD4 T cell and the B cell to which it provides help.

A second type of CD4 T cell has as its major function secreting the cytokines that contribute to the establishment

of an inflammatory environment. Multiple types of CD4 T cells have thus been defined based on the cytokines they produce and their functional properties. Whereas all activated T cells can produce IL-2, other cytokines are produced by particular CD4 T-cell subsets. These CD4 T cells are classified as T_H1 cells, characterized by the production of interferon γ and TNF, and T_H2 cells, characterized by the production of IL-4 and IL-10. T_H1 cells, through production of IFN γ , can activate macrophages and stimulate an inflammatory response. Referred to also as *inflammatory T cells*, T_H1 cells nonetheless play an important role in antibody production, notably facilitating the production of complement-fixing antibodies such as IgG1 and IgG3. T_H2 cells, through production of IL-4, play an important role in B-cell responses that involve class-switch recombination to the IgG1 and IgE isotypes (discussed below). The combination of cytokines produced by CD4 T cells, and the interaction between the CD40 protein induced on activated T cells with CD40 ligand (CD40L) on B cells, is responsible for induction of activation-induced deaminase, and so prepares the B cell for class-switch recombination and somatic hypermutation.

Recently discovered subsets of CD4 T cells include *regulatory T cells* and T_H17 cells. The former can attenuate immune responses by exerting a suppressive effect on cytokine production by other T cells. These regulatory T cells restrain the activity of potentially self-reactive T cells and are important in maintaining tolerance (the absence of an immune response to self antigens). T_H17 cells are important in host defense against bacteria and also play a role in autoimmune disease.

Leukocytes Move in Response to Chemotactic Cues Provided by Chemokines

Interleukins tell lymphocytes what to do by eliciting a transcriptional program that allows lymphocytes to acquire specialized effector functions. On the other hand, chemokines tell leukocytes where to go. Many cells emit chemotactic cues in the form of chemokines. When tissue damage occurs, resident fibroblasts produce a chemokine, IL-8, that attracts neutrophils to the site of damage. The regulation of lymphocyte trafficking within lymph nodes is essential for dendritic cells to attract T cells, and for T cells and B cells to meet. These trafficking steps are all controlled by chemokines.

There are approximately 40 distinct chemokines and more than a dozen chemokine receptors. One chemokine may bind to more than one receptor, and a single receptor can bind several different chemokines. This creates the possibility of generating a combinatorial code of chemotactic cues of great complexity. This code is used to allow the navigation of leukocytes from where they are generated, in the bone marrow, into the bloodstream for transport to their target destination.

Some chemokines direct lymphocytes to leave the circulation and take up residence in lymphoid organs. These migrations contribute to the population of lymphoid organs with the required sets of lymphocytes. Because these movements occur as part of normal lymphoid development, such chemokines are also referred to as *homeostatic chemokines*.

Those chemokines that serve the purpose of recruiting leukocytes to sites of inflammation and tissue damage are referred to as *inflammatory chemokines*.

Chemokine receptors are G protein-coupled receptors that function as an essential step in the regulation of cell adhesion and cell migration. Leukocytes that travel through blood vessels do so at high speed and are exposed to high hydrodynamic shear forces. For a leukocyte to traverse the endothelium and take up residence in a lymph node or seek out a site of infection in tissue, it must first slow down, a process that requires interactions of surface receptors called selectins with their ligands, which are mostly carbohydrate in nature. If chemokines are found in proximity, adsorbed to the extracellular matrix, and if the leukocyte possesses a receptor for that chemokine, activation of the chemokine receptor elicits a signal that allows integrins carried by the leukocyte to undergo a conformational change. This change results in an increase in affinity of the integrin for its ligand and causes firm arrest of the leukocyte. The leukocyte may now exit the blood vessel by a process known as *extravasation* (see Figure 20-39).

KEY CONCEPTS of Section 23.5

T Cells, T-Cell Receptors, and T-Cell Development

- The antigen-specific T-cell receptors are dimeric proteins consisting of α and β subunits or γ and δ subunits. T cells occur in at least two major classes based on the expression of the glycoprotein co-receptors CD4 and CD8 (see Figure 23-27).
- Cells that use class I MHC molecules as restriction elements carry CD8; those that use class II MHC molecules carry CD4. These classes of T cells are functionally distinct: CD8 T cells are cytotoxic T cells; CD4 T cells provide help to B cells and are an important source of cytokines.
- Genes encoding the TCR subunits are generated by somatic recombination of V and J segments (α chain) and of V, D, and J segments (β chain); their rearrangement obeys the same rules as those defined for rearrangement of Ig genes in B cells (see Figure 23-28). Rearrangement of TCR genes occurs in the thymus and only in those cells destined to become T lymphocytes.
- A complete T-cell receptor includes the accessory CD3 complex, which is required for signal transduction. Each subunit of the CD3 complex carries in its cytoplasmic tail one or three ITAM domains; when phosphorylated, these ITAMs recruit accessory molecules involved in signal transduction (see Figure 23-29).
- In the course of T-cell development, the TCR β locus rearranges first, encoding a functional β subunit that is incorporated in the pre-TCR, which also includes a specialized pre-TCR subunit encoded by an unrearranged gene (see Figure 23-30). Similar to the pre-BCR, the pre-TCR mediates allelic exclusion and proliferation of those cells that successfully underwent TCR β rearrangement.

- T cells destined to become CD8 T cells must interact with class I MHC molecules in the course of their development; those that will become CD4 T cells must interact with class II MHC molecules. Developing T cells that fail to recognize any MHC molecules at all die for lack of survival signals. T cells that interact too strongly with peptide-MHC complexes encountered during development are instructed to die (negative selection); those that have intermediate affinity for peptide-MHC complexes are allowed to mature (positive selection) and are exported from the thymus to the periphery.
- T cells are instructed where to go (cell migration) through chemotactic signals in the form of chemokines. Receptors for chemokines are G protein-coupled receptors that show some promiscuity in terms of their binding of chemokines. The complexity of the chemokine-chemokine receptor family allows precise regulation of leukocyte trafficking, both within lymphoid organs and in the periphery.

23.6 Collaboration of Immune-System Cells in the Adaptive Response

An effective adaptive immune response requires the presence of B cells, T cells, and antigen-presenting cells. For B cells to execute class-switch recombination and hypermutation—prerequisites for production of high-affinity antibodies—they require help from activated T cells. These T cells, in turn, can only be activated by professional antigen-presenting cells such as dendritic cells, which detect invaders using their Toll-like receptors (TLRs) and other pattern-recognition receptors, such as the C-type lectins that can recognize polysaccharides and carbohydrate determinants. The interplay between components of innate and adaptive immunity is therefore a very important aspect of adaptive immunity. This layered, interwoven nature of innate and adaptive immunity both ensures a rapid early response of immediate protective value and also primes the adaptive immune system for a specific response to any persisting invader. In this section we describe how these various elements are activated and how the relevant cell types interact.

Toll-Like Receptors Perceive a Variety of Pathogen-Derived Macromolecular Patterns

An important part of innate defenses is the ability to immediately detect the presence of a microbial invader and respond to it. This response includes direct elimination of the invader, but it also prepares the mammalian host for a proper adaptive immune response, in particular through activation of professional antigen-presenting cells. Antigen-presenting cells are positioned throughout the epithelia (airways, gastrointestinal tract, genital tract), where contact

with pathogens is most likely to occur. In the skin, a network of dendritic cells called *Langerhans cells* makes it virtually impossible for a pathogen that breaches this barrier to avoid contact with these professional antigen-presenting cells. Dendritic cells and other professional antigen-presenting cells detect the presence of bacteria and viruses through members of the Toll-like receptor (TLR) family. These proteins are named after the *Drosophila* protein Toll because of the structural and functional homology between them. *Drosophila* Toll was discovered because of its important role in dorsoventral patterning in the fruit fly, but related receptors are now recognized as capable of triggering an innate immune response in insects as well as in vertebrates.

TLR Structure Toll itself and all Toll-like receptors possess an extracellular domain composed of *leucine-rich repeats*. These repeats form a sickle-shaped extracellular domain believed to be involved in ligand recognition. The cytoplasmic portion of Toll-like receptors contains a domain responsible for the recruitment of adapter proteins to enable signal transduction. The signaling pathways engaged by the Toll-like receptors share many of the same components (and outcomes) as those used by receptors for the cytokine IL-1 (Figure 23-33).

The *Drosophila* Toll protein interacts with its ligand, Spaetzle, itself the product of a proteolytic conversion initiated by components of the cell wall of fungi that prey on *Drosophila*. In the fly, activation of Toll unleashes a signaling cascade that ultimately controls the transcription of genes that encode antimicrobial peptides. Although appreciated first as a cascade that controls early *Drosophila* development, it has since become clear that the Toll pathway also controls insect immunity. The activated receptor at the surface communicates with the transcriptional apparatus by means of a series of adapter proteins that activate downstream kinases interposed between the Toll-like receptor and the transcription factors that are activated by signaling from them. A key step is the ubiquitin-dependent proteasomal degradation of the Cactus protein. Its removal allows the protein Dif to enter the nucleus and initiate transcription. This pathway is highly homologous in its operation and structural composition to the NF- κ B pathway in mammals (see Figure 16-34).

Diversity of TLRs There are approximately a dozen mammalian Toll-like receptors that can be activated by various microbial products. These receptors are expressed by a variety of cell types, but their function is crucial for the activation of dendritic cells and macrophages. Neutrophils also express Toll-like receptors. The microbial products recognized by Toll-like receptors include macromolecules found in the cell envelope of bacteria such as lipopolysaccharides (LPS), flagellins (subunits of bacterial flagella), and bacterial lipopeptides. Direct binding of at least some of these macromolecules to Toll-like receptors has been shown directly through crystallographic analysis of the relevant complexes. The presence of

FIGURE 23-33 Toll-like receptor activation. The extracellular portions of TLRs recognize ligands of diverse chemical nature (nucleic acids, lipopolysaccharides). The cytoplasmic portions of the TLRs associate with the adapter molecule MyD88, present in six copies per complex, and recruit two types of kinase, both members of the IRAK family. These complex interactions are maintained via Toll/IL-1 β receptor (TIR) homology domains and death domains (DD), as indicated in the figure. The assembled complex on the cytoplasmic side is referred to as the Myddosome. [Adapted from J. Y. Kang and J.-O. Lee, 2011, *Ann. Rev. Biochem.* **80**:917.]

distinct classes of microbial molecules is sensed by distinct receptors: for example, TLR4 for lipopolysaccharide; heterodimeric of TLR1/2 and TLR2/6 for lipopeptides; and TLR5 for flagellin. Recognition of all bacterial envelope components occurs at the cell surface.

A second set of Toll-like receptors—TLR3, TLR7, and TLR9—sense the presence of pathogen-derived nucleic acids. They do so not at the cell surface, but rather within the endosomal compartments where these receptors reside. Mammalian DNA is methylated at many CpG dinucleotides, whereas microbial DNA generally lacks this modification. TLR9 is activated by unmethylated, CpG-containing microbial DNA. Similarly, double-stranded RNA molecules present in some virus-infected cells lead to activation of TLR3. Finally, TLR7 responds to the presence of certain single-stranded RNAs. Thus the full set of mammalian TLRs allows the recognition of a variety of macromolecules that are diagnostic for the presence of bacterial, viral, and fungal pathogens.

More recently a variety of intracellular receptors for RNA and DNA have been described that recognize viral RNA and are structurally distinct from TLRs. The list of cytoplasmic receptors capable of recognizing DNA, both pathogen derived and host DNA derived, continues to grow. Several of these receptors participate in the assembly of a structure called the inflammasome (Figure 23-34), whose major function is the conversion of procaspase-1 to active caspase-1. Caspase 1 is a pro-

tease that converts proIL-1 β into active IL-1 β , a cytokine that elicits a strong inflammatory response. Core components of inflammasomes are proteins with leucine-rich repeats, members of the neuronal inhibitors of apoptosis (NALP) family of proteins, and the NOD proteins, so named because of the presence of nucleotide oligomerization domain. Ipaf-1, a protein related to the Apaf-1 molecule involved in apoptosis (see Chapter 21), allows the recruitment of an adaptor, ASC, to mediate complex formation with procaspase-1. This allows the conversion of procaspase-1 to active caspase-1, and conversion of proIL-1 β to IL-1 β . Many seemingly unrelated substances can induce assembly and activation of an inflammasome, including silica, uric acid crystals, and asbestos particles. Accordingly, inhibition of the inflammasome signaling cascade, or blocking the receptor for IL-1 β , has shown therapeutic promise for a variety of inflammatory diseases.

TLR Signal Cascade As shown in Figure 23-33, engagement of mammalian Toll-like receptors leads to recruitment of the adapter protein MyD88, which in turn allows the binding and activation of IRAK (interleukin 1 receptor-associated kinase) proteins. After IRAK phosphorylates TNF-receptor-associated factor 6 (TRAF6), several downstream kinases come into play, leading to release of active NF- κ B, a transcription factor, for translocation from the cytoplasm to the

FIGURE 23-34 The inflammasome. The inflammasome is a structure that senses the presence of cytoplasmic pathogen-derived nucleic acids and can be also activated by other danger signals, including particulate matter such as uric acid crystals or even asbestos. There are close to two dozen proteins that can participate in the formation of these complexes to yield inflammasomes of different composition, two of which are represented schematically. Ultimately, the fully assembled inflammasome activates caspase-1, the enzyme that converts proIL-1 β into the active, cleaved form, IL-1 β . NALP3 = a member of the protein family characterized by the presence of NACHT, LRR, and PYD domains; ASC = apoptosis-associated speck-like protein containing a CARD caspase recruitment domain. [Adapted from http://www.unil.ch/webdav/site/ib/shared/Tschopp/Fig1_JT.jpg.]

nucleus, where NF- κ B activates various target genes (see Figure 16-35). These target genes include those encoding IL-1 β and IL-6, which contribute to inflammation, as well as the genes for tumor necrosis factor (TNF) and IL-12. Expression of type I interferons, small proteins with antiviral effects, is also turned on in response to TLR signaling.

Cell responses to TLR signaling are quite diverse. For antigen-presenting cells, these responses include not only production of cytokines but also the up-regulation of co-stimulatory molecules, the surface proteins important for full activation of naive T cells. TLR signaling allows dendritic cells to migrate from where they encounter a pathogen to the draining lymph nodes, where they may interact with naive lymphocytes. Not all activated Toll-like receptors evoke the identical response. Each activated TLR controls production of a particular set of cytokines by dendritic cells. For each engaged TLR, the combination of surface proteins and the cytokine profile induced by TLR engagement thus creates a unique phenotype for the activated dendritic cell. The identity of the microbe encountered sets the pattern of the TLRs that will be activated. These, in turn, shape the differentiation pathways of activated dendritic cells in terms of the cytokines produced, the surface molecules displayed, and the chemotactic cues to which the dendritic cells respond. The mode of activation of a dendritic cell and the cytokines it produces in response create a unique microenvironment in which T cells differentiate. Here they acquire the functional

characteristics required to fight the infectious agent that led to engagement of the TLRs in the first place.

Engagement of Toll-Like Receptors Leads to Activation of Antigen-Presenting Cells

Professional antigen-presenting cells engage in continuous endocytosis, and in the absence of pathogens, they display at their surface class I and class II MHC molecules loaded with peptides derived from self-proteins. In the presence of pathogens, the Toll-like receptors on these cells are activated, inducing the antigen-presenting cells to become motile: they detach from the surrounding substratum and start to migrate in the direction of the draining lymph node, where the directional cues are provided by chemokines. An activated dendritic cell, for example, reduces its rate of antigen acquisition, up-regulates the activity of endosomal/lysosomal proteases, and increases the transfer of class II MHC-peptide complexes from the loading compartments to the cell surface. Finally, activated professional antigen-presenting cells up-regulate expression of the co-stimulatory molecules CD80 and CD86, which will allow them to activate T cells more effectively. The initial contact of a professional antigen-presenting cell with a pathogen thus results in its migration to the draining lymph node in a state that is fully capable of activating a naive T cell. Antigen is displayed in the form of peptide-MHC complexes, co-stimulatory molecules are abundantly present, and cytokines are produced that assist in setting up the proper differentiation program for the T cells to be activated.

Antigen-laden dendritic cells engage antigen-specific T cells, which respond by proliferating and differentiating. The cytokines produced in the course of this priming reaction determine whether a CD4 T cell will polarize toward an inflammatory or a helper-cell phenotype. If engagement occurs via class I MHC molecules, a CD8 T cell may develop from a precursor cytotoxic T cell to a fully active cytotoxic T cell. The activated T cells are motile and move through the lymph node, in preparation for their encounter with B cells, or, in order to contact the vasculature, enter the circulation, and leave the lymph node to execute effector functions elsewhere in the body.

Production of High-Affinity Antibodies Requires Collaboration Between B and T Cells

To generate high-affinity antibodies, which are better at binding antigen and at neutralizing pathogens, B cells require assistance from T cells. Thus, B-cell activation requires a source of antigen to engage the B-cell receptor and the presence of activated antigen-specific T cells. Soluble antigen reaches the lymph node through the afferent lymphatics (see Figure 23-6). Bacterial growth is accompanied by the release of microbial products that can serve as antigens. If the infection is accompanied by local tissue destruction, activation of the complement cascade results in bacterial killing and concomitant release of bacterial proteins, which are also delivered via the lymphatics to the draining lymph node. Complement-modified

antigens are superior in the activation of B cells through engagement of complement receptors on B cells, which serve as co-receptors for the B-cell receptor. B cells that acquire antigen via their B-cell receptors internalize the immune complex and process it for presentation via the class II MHC pathway. Antigen-experienced B cells thus convert the BCR-acquired antigen into a call for T-cell help in the form of a class II MHC-peptide complex (Figure 23-35). Note that the epitope recognized by the B-cell receptor may be quite distinct from the peptide ultimately displayed on the surface associated with a class II MHC molecule. As long as the B-cell epitope and the class II-presented peptide—a T-cell epitope—are physically linked, successful B-cell differentiation can be initiated.

The concept of linked recognition explains why there is a minimum size for molecules that can be used to successfully elicit a high-affinity antibody response. Such molecules must fulfill several criteria: they must contain the epitope seen by the B-cell receptor, undergo endocytosis and proteolysis, and a proteolyzed fragment of the molecule must bind to the allelic class II MHC molecules available in order to be presented as a class II MHC-peptide complex, which serves as a call for T-cell help. For this reason, synthetic peptides used to elicit antibodies are conjugated to carrier proteins to improve their immunogenicity, where the carrier proteins serve as the source of peptides for presentation via class II MHC products. Only through recognition of this class II MHC-peptide complex via its T-cell receptor can T cells provide the help necessary for the B cell to run its complete course of differentiation.

This concept applies equally to B cells capable of recognizing particular modifications on proteins or peptides. Antibodies that recognize the phosphorylated form of a kinase are commonly raised by immunization of experimental animals with the phosphorylated peptide in question, conjugated to a carrier protein. An appropriately specific B cell recognizes the phosphorylated site on the peptide of interest, internalizes the phosphorylated peptide and carrier, and generates a complex set of peptides by endosomal proteolysis of the carrier protein. Among these peptides there should be at least one that can bind to the class II MHC molecules carried by that B cell for a successful response to ensue. If properly displayed at the surface of the B cell, this class II MHC-peptide complex becomes the call for T-cell help, provided by CD4 T cells equipped with receptors capable of recognizing the complex of class II MHC molecule and carrier-derived peptide.

The T cell identifies, via its T-cell receptor, an antigen-experienced B cell by means of the class II MHC-peptide complexes displayed by the B cell. The B cell also displays costimulatory molecules and receptors for cytokines produced by the activated T cell (e.g., IL-4). These B cells then proliferate. Some of them differentiate into plasma cells; others are set aside and become memory B cells. The first wave of antibodies produced is always IgM. Class switching to other isotypes and somatic hypermutation (necessary for the generation and selection of high-affinity antibodies) requires the persistence of antigen or repeated exposure to antigen. In addition to cytokines, B cells require cell-cell contacts to initiate somatic hypermutation and class-switch recombina-

tion. These contacts involve CD40 protein on B cells and CD40L on T cells. These proteins are members of the TNF-TNF receptor family.

Vaccines Elicit Protective Immunity Against a Variety of Pathogens

 Arguably the most important application of immunological principles is vaccines. Vaccines are materials designed to be innocuous but that can elicit an immune response for the purpose of providing protection against a challenge with the virulent version of that pathogen (Figure 23-36). It is not always known why such vaccines are as successful as they are, but in many cases, the ability to raise antibodies that can neutralize the pathogen (viruses) or that show microbicidal effects (bacteria) are good indicators of successful vaccination.

Several strategies can lead to a successful vaccine. Vaccines may be composed of live attenuated variants of more virulent pathogens. Serial passage in tissue culture or from animal to animal will often lead to *attenuation*, the molecular basis for which is not well understood. The attenuated version of the pathogen causes a mild form of the disease or causes no symptoms at all. However, by recruiting all the component parts of the adaptive immune system, such live attenuated vaccines can elicit protective levels of antibodies. These antibody levels may wane with advancing age; and repeated immunizations (booster injections) are often required to maintain full protection. Live attenuated vaccines are in use against flu, measles, mumps, and tuberculosis. In the latter case, an attenuated strain of the mycobacterium that causes the diseases is used (Bacille Calmette-Guerin; BCG). Although live attenuated poliovirus was used as a vaccine until recently, its use was discontinued because the risk of re-emergence of more virulent strains of the poliovirus outweighed the benefit. Currently, killed poliovirus is used as the vaccine of choice.

Vaccines based on the cowpox virus, a close relative of the human pathogen variola responsible for smallpox, have been used successfully to completely eradicate smallpox, the first such example of the elimination of an infectious disease. Attempts to achieve a similar feat for polio are nearing completion.

The other major type of vaccine is called a subunit vaccine. Rather than using live attenuated strains of a virulent bacterium or virus, only one of its components is used to elicit immunity. In certain cases this is sufficient to afford lasting protection against a challenge with the live, virulent source of the antigen used for vaccination. This approach has been successful in preventing infections with the hepatitis B virus. The commonly used flu vaccines are composed mostly of the envelope proteins neuraminidase and hemagglutinin (see Figure 3-10); these vaccines elicit neutralizing antibodies. For the human papillomavirus HPV 16, a serotype that causes cervical cancer, viruslike particles are generated that are composed of the virus capsid proteins but devoid of its genetic material; these viruslike particles are noninfectious, yet in many respects mimic the intact virion. The HPV vaccine now licensed for use in humans is expected to reduce the

FIGURE 23-35 Collaboration between T and B cells is required to initiate the production of antibodies. *Left:* Activation of T cells by means of antigen-loaded dendritic cells (DCs). *Right:* Antigen acquisition by and subsequent activation of B cells. **Step 1:** Professional antigen-presenting cells (DCs, B cells) acquire antigen. **Step 2:** Antigen is internalized, processed, and presented to T cells. T-cell activation occurs when dendritic cells present antigen to T cells. **Step 3a:** Activated T cells engage antigen-experienced B cells through peptide-MHC complexes displayed on the surface of the B cell. **Step 3b:** T cells

that are persistently activated initiate expression of the CD40 ligand (CD40L), a prerequisite for B cells becoming fully activated and turning on the enzymatic machinery (activation-induced deaminase) to initiate class-switch recombination and somatic hypermutation. **Step 4a:** A B cell that receives the appropriate instructions from CD4 helper T cells becomes an IgM-secreting plasma cell. **Step 4b:** A B cell that receives signals from activated CD4 helper T cells in the form of CD40-CD40L interactions and the appropriate cytokines can class switch to other immunoglobulin isotypes and engage in somatic hypermutation.

FIGURE 23-36 Time course of a viral infection. The initial antiviral response, seen when the numbers of infectious particles rises, includes activation of natural killer (NK) cells and production of type I interferons. These responses are part of innate defenses. The production of antibodies, as well as the activation of cytotoxic T cells (CTLs), follows, and eventually clears the infection. Re-exposure to the same virus leads to more rapid and more pronounced production of antibodies and to more rapid activation of cytotoxic T cells. A successful vaccine induces an immune response similar in some respects to that following initial exposure to a pathogen, but without causing significant symptoms of disease. If a vaccinated person subsequently is exposed to that pathogen, the adaptive immune system is primed to respond quickly and strongly.

incidence of cervical cancer in susceptible populations by perhaps as much as 80 percent, the first example of a vaccine that prevents this particular type of cancer.

From a public health perspective, cheaply produced and widely distributed vaccines are formidable tools in eradicating communicable diseases. Current efforts are aimed at producing vaccines against diseases for which no other suitable therapies are available (Ebola virus) or where socioeconomic conditions have made distribution of drugs problematic (malaria, HIV/AIDS). Through a more complete understanding of how the immune system operates, it should be possible to improve on the design of existing vaccines and extend these principles to diseases for which currently no successful vaccines are available. ■

KEY CONCEPTS of Section 23.6

Collaboration of Immune-System Cells in the Adaptive Immune Response

- Antigen-presenting cells such as dendritic cells require activation by means of signals delivered to their Toll-like receptors. These receptors are broadly specific for macromolecules

produced by bacteria and viruses. Engagement of Toll-like receptors activates the NF- κ B signaling pathway, whose outputs include the synthesis of inflammatory cytokines (see Figure 23-33).

- Upon activation, dendritic cells become migratory and move to lymph nodes, ready for their encounter with T cells. Activation of dendritic cells also increases their display of MHC-peptide complexes and expression of co-stimulatory molecules required for initiation of a T-cell response.
- B cells require assistance of activated T cells to execute their full differentiation program to become plasma cells. Antigen-specific help is provided to B cells by activated T cells, which recognize class II MHC-peptide complexes on the surface of B cells. These B cells generate the relevant MHC-peptide complexes by internalizing antigen via BCR-mediated endocytosis, followed by antigen processing and presentation via the class II MHC pathway (see Figure 23-35).
- In addition to cytokines produced by activated T cells, B cells require cell-cell contact to initiate somatic hypermutation and class-switch recombination. This involves CD40 on B cells and CD40L on T cells.
- Important applications of the immunological concept of collaboration between T and B cells include vaccines. The most common forms of vaccines are live attenuated viruses or bacteria, which can evoke a protective immune response without causing pathology, and subunit based vaccines.

Perspectives for the Future

Several areas of immunological research promise to have a major impact. The generation of new vaccines that are both safe and effective remains a goal of enormous practical and societal significance: HIV infection, drug-resistant tuberculosis, and malaria are three examples of major killers, each responsible for millions of deaths annually, for which no successful vaccines are currently available. Research must incorporate cell biological as well as immunological concepts to solve this unmet need. Even though some of the most successful vaccines were developed in the absence of detailed immunological knowledge, the current regulatory climate demands a more detailed understanding of the composition of a successful vaccine and why such vaccines work.

Lymphocytes are among the few cell types that can be studied as primary cells that continue to perform cell- and tissue-type specific behavior in tissue culture. This trait makes lymphocytes an attractive model in which to study details of signal transduction, to explore interactions between well-defined, different cell types under defined laboratory conditions, and to accurately measure and model the responses evoked by specific stimuli.

The ability of lymphocytes to create antigen-specific receptors of nearly limitless variability comes at a price: the generation of self-reactive receptors, which is the major contributing factor to autoimmune disease. Vertebrates have

several mechanisms for keeping such self-reactive lymphocytes in check, but none of them is foolproof. We must understand how tolerance to self-antigens is generated, maintained, and ultimately broken at the onset of autoimmune disease. This understanding should help define new strategies for manipulating and controlling self-reactive lymphocytes to prevent or treat autoimmune diseases (e.g., type I diabetes, multiple sclerosis, and arthritis).

With advances in understanding of stem cells and how to use stem cells for therapy in the treatment of diseases (e.g., Parkinson's disease, muscular dystrophy, and spinal cord injuries), transplantation of heterologous stem cells (i.e., derived from an individual other than the patient) is one of several options. The immune system's ability to recognize as foreign such transplanted stem-cell derivatives is a factor that will limit the use of heterologous stem cells. Consequently, new means to suppress responses to these transplants, or to induce tolerance to them, are important goals.

More refined genetic tools continue to allow identification of additional lymphocyte subsets, often with distinct functions. Improved classification schemes will help in understanding lymphocyte function, and so open the door to selective manipulation of lymphocyte function for therapeutic gain.

Our understanding of the interplay between innate and adaptive immune responses, and the many ways in which pathogens interfere in both innate and adaptive immunity, will benefit from our increased understanding of genome sequences and genome structures, both host and pathogen. The use of genetically modified pathogenic organisms as probes for host immune function will help our understanding of basic immunology. This is a rapidly expanding area of basic cell biological research.

Review the Concepts

1. Describe the ways in which each of the following pathogens can disarm or manipulate their host's immune system to their own advantage: (a) pathogenic strains of *Staphylococcus aureus* and (b) enveloped viruses.
2. Trace the course of leukocytes as they perform their functions throughout the body.
3. Identify the major mechanical and chemical defenses that protect internal tissues from microbial attack.
4. Compare/contrast the classical pathway of complement activation to the alternative pathway.
5. What evidence led Emil von Behring to discover antibodies and the complement system in 1905?
6. What is opsonization? What is the role of antibodies in this process?
7. In B cells, what mechanism ensures that only rearranged V genes are transcribed?
8. What prevents further rearrangement of immunoglobulin heavy-chain gene segments in a pre-B cell once a productive heavy-chain rearrangement has occurred?
9. How/why do antibodies undergo a class switch from producing IgM antibodies to any of the other isotypes?
10. What biochemical mechanism underlies affinity maturation of the antibody response?
11. Compare/contrast the structures of class I and class II MHC molecules. What kinds of cells express each class of MHC molecule? What are their functions?
12. Describe the six steps in antigen processing and presentation via the class I MHC restricted pathway.
13. Describe the six steps in antigen processing and presentation via the class II MHC restricted pathway.
14. What prevents self-reactive T cells from leaving the thymus?
15. Explain why T-cell-mediated autoimmune diseases are associated with particular alleles of class II MHC genes.
16. How are antigen-presenting cells and helper T cells involved in B-cell activation?
17. Outline the events in the innate and adaptive immune responses, from when a pathogen invades to clearance of the pathogen.
18. Define passive immunization and give an example.
19. How would you design a vaccine that protects against HIV infection without the possibility of infecting the patient?
20. The annual flu shot is composed of either a live attenuated virus or influenza subunits (envelope proteins neuraminidase and hemagglutinin). How does the annual flu shot protect you against infection?

21. Design a laboratory protocol to develop a monoclonal or polyclonal antibody against a protein of interest.
22. Consider a person without any functioning plasma cells. What effects would this have on the person's adaptive immune system? Innate immune system?

Analyze the Data

To understand how ovalbumin (a protein from chicken eggs) and other foreign antigens in the cytoplasm of a cell are presented for immunosurveillance, ovalbumin can be introduced by electroporation into the cytoplasm of mouse primary B lymphocytes. The ovalbumin is cleaved, and one of its cleavage products is a peptide with the sequence SIINFEKL (single-letter abbreviations). When these B cells are mixed with a clonal T-cell population that specifically recognizes SIINFEKL in the context of MHC molecules, the T cells become stimulated. The graphs below show the secretion of IL-2 after these T cells were mixed with B cells that had been treated in various ways.

Graph A: B cells were electroporated either with ovalbumin (solid line) or with a control protein (dashed line) not recognized by this clonal T-cell population.

Graph B: B cells were first incubated with an inhibitor of lysosomal cysteine proteases (solid line) or an inhibitor of the proteasome (dashed line) and then electroporated with ovalbumin.

Graph C: B cells were exposed to a high concentration of the SIINFEKL peptide and then immediately fixed [killed]

(dotted line) with formaldehyde or incubated for 2 hours in the presence (dashed curve) or absence (solid curve) of the proteasome inhibitor and then fixed with formaldehyde.

a. Under what conditions is IL-2 secreted? Is it likely that the T cells or the B cells are secreting IL-2?

b. What information is derived from the use of the lysosomal and the proteasome inhibitors? Is the ovalbumin peptide more likely to be presented complexed with class I MHC or class II MHC molecules? What is the most likely pathway by which ovalbumin in the cytoplasm of the B cell is presented for recognition by the appropriate T cells?

c. Why do you think that the presence or absence of the proteasome inhibitor in experiment C had no effect on the amount of IL-2 secreted, whereas the presence of the inhibitor in experiment B shows a marked effect?

Two Genes Become One: Somatic Rearrangement of Immunoglobulin Genes

N. Hozumi and S. Tonegawa, 1976, *Proc. Nat'l Acad. Sci. USA* 73:3629

For decades, immunologists wondered how the body could generate the multitude of pathogen-fighting immunoglobulins, called antibodies, needed to ward off the vast array of different bacteria and viruses encountered in a lifetime. Clearly, these protective proteins, like all proteins, somehow were encoded in the genome. But the enormous number of different antibodies potentially produced by the immune system made it unlikely that individual immunoglobulin (Ig) genes encoded all the possible antibodies an individual might need. In studies beginning in the early 1970s, Susumu Tonegawa, a molecular biologist, laid the foundation for solving the mystery of how antibody diversity is generated.

Background

Research on the structure of Ig molecules provided some clues about the generation of antibody diversity. First, it was shown that an Ig molecule is composed of four polypeptide chains: two identical heavy (H) chains and two identical light (L) chains. Some researchers proposed that antibody diversity resulted from different combinations of heavy and light chains. Although somewhat reducing the number of genes needed, this hypothesis still required that a large portion of the genome be devoted to Ig genes. Protein chemists then sequenced several Ig light and heavy chains. They found that the C-terminal regions of different light chains were very similar and thus were termed the constant (C) region, whereas the N-terminal regions were highly variable and thus were termed the variable (V) region. The sequences of different heavy chains exhibited a similar pattern. These findings suggested that the genome contains a small number of C genes and a much larger group of V genes.

In 1965, W. Dryer and J. Bennett proposed that two separate genes, one V gene and one C gene, encode each heavy chain and each light chain. Although this proposal seemed logical, it violated the well-documented principle that each gene encodes a single polypeptide. To avoid this objection, Dryer and Bennett suggested that a V and C gene somehow were rearranged in the genome to form a single gene, which then was transcribed and translated into a single polypeptide, either a heavy or light chain. Indirect support for this model came from DNA hybridization studies showing that only a small number of genes encoded Ig constant regions. However, until more powerful techniques for analyzing genes came on the scene, a definitive test of the novel two-gene model was not possible.

The Experiment

Tonegawa realized that if immunoglobulin genes underwent rearrangement, then the V and C genes were most likely located at different points in the genome. The discovery of restriction endonucleases, enzymes that cleave DNA at specific sites, had allowed some bacterial genes to be mapped. However, because mammalian genomes are much more complex, similar mapping of the genes encoding V and C regions was not technically feasible. Instead, drawing on newly developed molecular biology techniques, Tonegawa devised another approach for determining whether the V and C regions were encoded by two separate genes. He reasoned that if rearrangement of the V and C genes occurs, it must happen during differentiation of Ig-secreting B cells from embryonic cells. Furthermore, if rearrangement occurs, there should be detectable differences between unrearranged germline DNA from embryonic cells and

the DNA from Ig-secreting B cells. Thus, he set out to see if such differences existed using a combination of restriction-enzyme digestion and RNA-DNA hybridization to detect the DNA fragments.

He began by isolating genomic DNA from mouse embryos and from mouse B cells. To simplify the analysis, he used a line of B-cell tumor cells, all of which produce the same type of antibody. The genomic DNA was then digested with the restriction enzyme *Bam*HI, which recognizes a sequence that occurs relatively rarely in mammalian genomes. Thus, the DNA was broken into many large fragments. He then separated these DNA fragments by agarose gel electrophoresis, which separates biomolecules on the basis of charge and size. Since all DNA carries an overall negative charge, the fragments were separated based on their size. Next, he cut the gel into small slices and isolated the DNA from each slice. Now, Tonegawa had many fractions of DNA pieces of various sizes. He then could analyze these DNA fractions to determine if the V and C genes resided on the same fragment in both B cells and embryonic cells.

To perform this analysis, Tonegawa first isolated from the B-cell tumor cells the mRNA encoding the major type of Ig light chain, called κ . Since an RNA is complementary to one strand of the DNA from which it is transcribed, it can hybridize with this strand, forming a RNA-DNA hybrid. By radioactively labeling the entire κ mRNA, Tonegawa produced a probe for detecting which of the separated DNA fragments contained the κ -chain gene. He then isolated the 3' end of the κ mRNA and labeled it, yielding a second probe that would detect only the DNA sequences encoding the constant region of the κ chain. With these probes in hand—one specific for the combined V + C gene and one specific for C

Embryo DNA

FIGURE 1 Experimental results showing that the genes encoding the variable (V) and constant (C) regions of κ light chains are rearranged during development of B cells. These curves depict the hybridization of labeled RNA probes, specific for the entire κ gene (V + C)

alone—Tonegawa was ready to compare the DNA fragments obtained from B cells and embryonic cells.

He first denatured the DNA in each of the fractions into single strands and then added one or the other labeled probe. He found that the C-specific probe hybridized to different fractions derived from embryonic and B-cell DNA (Figure 1). Even more telling, the full-length RNA probe hybridized to two *different* fractions of the embryonic DNA, suggesting that the V and C genes are not connected and that a cleavage site for *Bam*HI lies between them. Tonegawa concluded that

during the formation of B cells, separate genes encoding the V and C regions are rearranged into a single DNA sequence encoding the entire κ light chain (Figure 2).

Discussion

The generation of antibody diversity was a problem awaiting development of powerful molecular techniques to answer it. Tonegawa went on to clone V-region genes and prove that the rearrangement must occur somatically. These findings affected genetics as well as immunology. Whereas once it

B-Cell DNA

and for the 3' end that encodes the C region, to fractions of digested embryonic or B-cell DNA separated by agarose gel electrophoresis. [Adapted from N. Hozumi and S. Tonegawa, 1976, *Proc. Nat'l Acad. Sci. USA* 73:3629.]

was believed that every cell in the body contained the same genetic information, it became clear that some cells take that information and alter it to suit other purposes. In addition to somatic rearrangement, Ig genes undergo a variety of other alterations that allow the immune system to create the diverse repertoire of antibodies necessary to react to any invading organism. Our current understanding of these mechanisms rests on the foundation of Tonegawa's fundamental discovery. For this work, he received the Nobel Prize for Physiology and Medicine in 1987.

FIGURE 2 Schematic diagram of κ light-chain DNA in embryonic cells and B cells that is consistent with Tonegawa's results. In embryonic cells, cleavage with the *Bam*HI restriction enzymes (red arrows) produces two different sized fragments, one containing the V gene and one containing the C gene. In B cells, the DNA is rearranged so that the V and C genes are adjacent, with no intervening cleavage site. *Bam*HI digestion thus yields one fragment that contains both the V and C genes.

Nasopharyngeal carcinoma (NPC). NPC is a malignant tumor arising from the mucosal epithelium of the nasopharynx, the uppermost part of the throat. NPCs can arise due to cigarette smoking, eating nitrosamine-rich foods (such as salt-cured fish), or are the result of an Epstein-Barr Virus (EBV) infection. The section showing the NPC is stained with hematoxylin and eosin. [Biophoto Associates/Photo Researchers].

Cancer

Cancer causes about one-fifth of the deaths in the United States each year. Worldwide, between 100 and 350 out of 100,000 people die of cancer each year. Cancer is due to failures of the mechanisms that usually control the growth and proliferation of cells. During normal development and throughout adult life, intricate genetic control systems regulate the balance between cell birth and death in response to growth signals, growth-inhibiting signals, and death signals. Cell birth and death rates determine adult body size and the rate of growth in reaching that size. In some adult tissues, cell proliferation occurs continuously as a constant tissue-renewal strategy. Intestinal epithelial cells, for instance, live for just a few days before they die and are replaced; certain white blood cells are replaced as rapidly, and skin cells commonly survive for only 2–4 weeks before being shed. The cells in many adult tissues, however, normally do not proliferate except during healing processes. Such stable cells (e.g., hepatocytes, heart muscle cells, neurons) can remain functional for long periods or even for the entire lifetime of an organism. Cancer occurs when the mechanisms that maintain these normal growth rates malfunction to cause excess cell division.

The losses of cellular regulation that give rise to most or all cases of cancer are due to genetic damage that is often

accompanied by influences of tumor-promoting chemicals, hormones, and sometimes viruses (Figure 24-1). Mutations in two broad classes of genes have been implicated in the onset of cancer: **proto-oncogenes** and **tumor-suppressor genes**. Proto-oncogenes normally promote cell growth; mutations change them into **oncogenes** whose products are excessively active in growth promotion. Oncogenic mutations usually result in either increased gene expression or production of a hyperactive product. Tumor-suppressor genes normally restrain growth, so mutations that inactivate them allow inappropriate cell division. A third, more specialized class of genes called **caretaker genes** is also often linked to cancer. Caretaker genes normally protect the integrity of the genome; when they are inactivated, cells acquire additional mutations at an increased rate—including mutations that cause the deregulation of cell growth and proliferation and lead to cancer. Many of the genes in these three classes encode proteins that help regulate cell proliferation (i.e., entry into and progression through the cell cycle) or cell death by **apoptosis**; others encode proteins that participate in repairing damaged DNA.

Cancer commonly results from mutations that arise during a lifetime's exposure to **carcinogens**, substances encountered in the environment, which include certain chemicals and

FIGURE 24-1 Overview of changes in cells that cause cancer.

During carcinogenesis, six fundamental cellular properties are altered, as shown here in this tumor growing within normal tissue, to give rise to the complete, most destructive cancer phenotype. Less dangerous tumors arise when only some of these changes occur. In this chapter we examine the genetic changes that result in these altered cellular properties.

[Adapted from Hanahan, D., and R. A. Weinberg, 2011, *Cell* 144:646–674.]

radiation. Most cancer cells have lost one or more genome maintenance and repair systems due to mutation, which may explain the large number of additional mutations they accumulate. Although DNA-repair enzymes do not directly inhibit cell proliferation, cells that have lost the ability to repair errors, gaps, or broken ends in DNA accumulate mutations in many genes, including those that are critical in controlling cell growth and proliferation. Thus loss-of-function mutations in caretaker genes such as the genes encoding DNA-repair enzymes prevent cells from correcting mutations that inactivate tumor-suppressor genes or activate oncogenes.

Cancer-causing mutations occur mostly in somatic cells, not in the germ-line cells, and somatic-cell mutations are not passed on to the next generation. However, certain inherited mutations, which are carried in the germ line, increase the probability that cancer will occur at some time. In a destructive partnership, somatic mutations can combine with inherited mutations to cause cancer.

The cancer-forming process, called *oncogenesis* or *tumorigenesis*, is an interplay between genetics and the environment. Most cancers arise after genes are altered by carcinogens or by errors in the copying and repair of genes. Even if the genetic damage occurs only in one somatic cell, division of this cell will transmit the damage to its daughter cells, giving rise to a clone of altered cells. Rarely, however, does mutation in a single gene lead to the onset of cancer. More typically, a series of mutations in multiple genes creates a progressively more rapidly proliferating cell type that escapes normal growth restraints, creating an opportunity for additional mutations. The cells also acquire other properties that give them an advantage, such as the ability to escape from normal epithelia and stimulate the growth of vasculature to obtain oxygen. Eventually the clone of cells grows into a **tumor**. In some cases cells from the primary tumor migrate to new sites, where they form secondary tumors, a process termed **metastasis**. Most cancer deaths are due to invasive, fast-growing metastasized tumors.

Metastasis is a complex process with many steps. It is facilitated by the tumor cells producing their own growth factors and angiogenesis factors (inducers of blood vessel growth). Motile, invasive cells are the most dangerous. Tissues that produce growth factors and readily grow new vasculature, such as bone, blood vessels, and liver, are the most vulnerable to invasion since these characteristics help to support the invaders.

Time plays an important role in cancer. Many years may be required to accumulate the multiple mutations that are required to form a tumor, so most cancers develop later in life. The requirement for multiple mutations also lowers

the frequency of cancer compared with what it would be if tumorigenesis were triggered by a single mutation. However, huge numbers of cells are, in essence, mutagenized and tested for altered growth during our lifetimes, a powerful selection in favor of these cells, which, in this case, we do not want. Cells that proliferate quickly become more abundant, undergo further genetic changes, and can become progressively more dangerous. Furthermore, cancer occurs most frequently after the age of reproduction and therefore plays a lesser role in reproductive success. So cancer is common, in part reflecting increasingly long human lives but also reflecting the lack of evolutionary selection against the disease.

In this chapter, we first introduce the properties of tumor cells and describe the multistep process of oncogenesis. Next, we consider the general types of genetic changes that lead to the unique characteristics of cancer cells and the interplay between somatic and inherited mutations. The following sections examine in detail how mutations affecting both growth-promoting and growth-inhibiting processes can result in excess cell proliferation. We conclude the chapter with a discussion of the role of carcinogens and how a breakdown in DNA-repair mechanisms due to the loss of caretaker genes can lead to oncogenesis.

24.1 Tumor Cells and the Onset of Cancer

Before examining in detail the genetic basis of cancer, we consider the general process of tumorigenesis and the properties of tumor cells that distinguish them from normal cells.

FIGURE 24-2 Gross and microscopic views of a tumor invading normal liver tissue. (a) The gross morphology of a human liver in which a metastatic lung tumor is growing. The white protrusions on the surface of

the liver are the tumor masses. (b) A light micrograph of a section of the tumor in (a) showing areas of small, dark-staining tumor cells invading a region of larger, light-staining, normal liver cells. [Courtesy of J. Braun.]

The change from a normal cell into a cancer cell commonly involves multiple steps, each one adding properties that make cells more likely to grow into a tumor. The genetic changes that underlie oncogenesis alter several fundamental properties of cells, allowing cells to evade normal growth controls and ultimately conferring the full cancer phenotype (see Figure 24-1). Cancer cells acquire a drive to proliferate that does not require an external inducing signal. They fail to sense signals that restrict cell division and continue to live when they should die. They often change their attachment to surrounding cells or the extracellular matrix, breaking loose to move away and spread the tumor. A cancer cell may, up to a point, resemble a particular type of normal, rapidly dividing cell, but the cancer cell and its progeny will be immortal. Tumors are characteristically *hypoxic* (oxygen starved), so to grow to more than a small size, tumors must obtain a blood supply. They often do so by signaling to induce the growth of blood vessels into the tumor. As cancer progresses, tumors become an abnormal organ, increasingly well adapted to growth and invasion of surrounding tissues.

Normal animal cells are often classified according to their embryonic tissue of origin, and the naming of tumors has followed suit. Malignant tumors are classified as *carcinomas* if they derive from epithelia such as endoderm (gut epithelium) or ectoderm (skin and neural epithelia) and *sarcomas* if they derive from mesoderm (muscle, blood, and connective tissue precursors). Carcinomas are by far the most common type of malignant tumor (more than 90 percent). Most tumors are solid masses, but the *leukemias*, a class of sarcomas, grow as individual cells in the blood. (The name *leukemia* is derived from the Latin for “white blood”: the massive proliferation of leukemic cells can cause a patient’s blood to appear milky.) The *lymphomas*, another type of malignant sarcoma, are solid tumors of lymphocytes and plasma cells. Malignant brain tumors can be derived from neural cells, and *glioblastomas* are tumors of the glial cells that constitute the major cell type in the brain.

Metastatic Tumor Cells Are Invasive and Can Spread

Tumors arise with great frequency, especially in older individuals, but most pose little risk to their host because they are localized and of small size. We call such tumors **benign**; an example is a wart, a benign skin tumor. The cells composing benign tumors closely resemble and may function like normal cells. The cell-adhesion molecules that hold tissues together keep benign tumor cells, like normal cells, localized to the tissues where they originate. A fibrous capsule usually delineates the extent of a benign tumor and makes it an easy target for a surgeon. Benign tumors become serious medical problems only if their sheer bulk interferes with normal functions or if they secrete excess amounts of biologically active substances such as hormones. Acromegaly, the overgrowth of head, hands, and feet, for example, can occur when a benign pituitary tumor causes overproduction of growth hormone.

In contrast, cells composing a **malignant** (cancerous) tumor (Figure 24-2), usually grow and divide more rapidly than normal cells and fail to die at the normal rate. A key characteristic of malignant cells is their ability to invade nearby tissue, spreading and seeding additional tumors while the cells continue to proliferate. Some malignant tumors, such as those in the ovary or breast, remain localized and encapsulated, at least for a time. When these tumors progress, the cells invade surrounding tissues and undergo metastasis (Figure 24-3a). Most malignant cells eventually acquire the ability to metastasize. Thus the major characteristics that differentiate metastatic (or malignant) tumors from benign ones are their abilities to invade nearby tissues and spread to distant sites in the body.

Normal cells are restricted to their place in an organ or tissue by cell-cell adhesion and by physical barriers such as the *basement membrane*, which underlies layers of epithelial cells and also surrounds the endothelial cells of blood vessels (see Chapter 20). In contrast, cancer cells have acquired the ability to penetrate the basement membrane using a cell protrusion

FIGURE 24-3 Metastasis. (a) First steps in metastasis, using breast carcinoma cells as an example. Cancer cells leave the main tumor and attack the basement membrane, using extracellular matrix (ECM) fibers to reach the blood vessels. The cancer cells can be attracted by signals such as epidermal growth factor (EGF), which can be secreted by macrophages (yellow). At the blood vessels they penetrate the layer of endothelial cells that forms the vessel walls and enter the bloodstream. (b) Carcinoma cells penetrate the extracellular matrix and blood vessel wall by extending “invadopodia,” which produce matrix metalloproteases and other proteases to open up a path. [Adapted from Yamaguchi et al., 2005, *Curr. Opin. Cell Biol.* 17:559.]

called an “invadopodium” and to migrate to distant sites in the body (Figure 24-3b). A developmental process known as the **epithelial-to-mesenchymal transition (EMT)** is thought to play a crucial role during the process of metastasis in some cancers. During normal development, the conversion of epithelial cells into mesenchymal cells is a step in the formation of some organs and tissues. An EMT requires distinct changes in patterns of gene expression and results in fundamental changes in cell morphology, such as loss of cell-cell adhesion, loss of cell polarity, and the acquisition of migratory and invasive properties. During metastasis, the EMT regulatory pathways are thought to be activated at the invasive front of tumors, producing single migratory cells. At the heart of the EMT are two transcription factors, Snail and Twist. These transcription factors promote expression of genes involved in cell migration, trigger down-regulation of cell adhesion factors such as E-cadherin, and increase the production of proteases that digest the basement membrane, thus allowing its penetration by the tumor cells. For example, many tumor cells secrete a protein (plasminogen activator) that converts the serum protein plasminogen to the active protease plasmin. Importantly, expression of many important drivers of the EMT,

such as SNAIL1 and SNAIL2, has been shown to correlate with disease relapse and patient survival in many cancers, including breast, colon, and ovarian cancer. The occurrence of the EMT indicates poor clinical outcome.

As the basement membrane disintegrates, some tumor cells will enter the bloodstream, but fewer than 1 in 10,000 cells that escape the primary tumor survive to colonize another tissue and form a secondary, metastatic tumor. Much of preventative medicine is currently focused on developing methods to identify the rare tumor cells that circulate in the bloodstream. The ability to capture the *circulating tumor cells (CTCs)* would provide not only a powerful and noninvasive tool for the early detection of cancer, but their analysis could provide insights into the nature of the disease and inform treatment.

In addition to escaping the original tumor and entering the blood, cells that will seed new tumors must then adhere to an endothelial cell lining a capillary and migrate across or through it into the underlying tissue in a process called **extravasation** (see Chapter 20). The multiple crossings of tissue layers that underlie malignancy require significant changes in the cells’ behavior and often involve new or variant surface proteins made by malignant cells.

Cancers Usually Originate in Proliferating Cells

In order for most oncogenic mutations to induce cancer, they must occur in dividing cells so that the mutation is passed on to many progeny cells. When such mutations occur in nondividing cells (e.g., neurons and muscle cells), they generally do not induce cancer, which is why tumors of muscle and nerve cells are rare in adults. Nonetheless, cancer does occur in tissues composed mainly of nondividing differentiated cells such as erythrocytes and most white blood cells, absorptive cells that line the small intestine, and keratinized cells that form the skin. It has therefore been suggested that the cells that initiate the tumors are not the differentiated cells themselves but rather their precursor cells. Fully differentiated cells usually do not divide. As they die or wear out, they are continually replaced by proliferation and differentiation of **stem cells**, and these cells are thought to be capable of transforming into tumor cells. Because stem cells can divide continually over the life of an organism, oncogenic mutations in their DNA can accumulate, eventually transforming them into cancer cells. Cells that have acquired these mutations have an abnormal proliferative capacity and generally cannot undergo normal processes of differentiation. In recent years it has also become clear that tumor-promoting mutations have the ability to transform a nondividing, terminally differentiated cell into a proliferating cell with precursor-like properties. Thus, in some cancers, dedifferentiation and the return of a cell to a precursor-like state could be the tumor-initiating event. Irrespective of whether tumors originate from differentiated cells that have regained the ability to proliferate or through mutation of tissue stem cells, it is now evident that in many tumors, like in normal organs, there are only certain cells with the ability to divide uncontrollably and generate new tumors; such cells are *cancer stem cells*, discussed in the next section.

Local Environment Impacts Heterogeneous Tumor Formation by Cancer Stem Cells

Some types of tumors appear to have their own stem cells; that is, these are the only tumor cells capable of seeding a new tumor. The concept is that within a tumor, some cells will cease dividing while others can continue cancerous growth. The latter, of course, are the most dangerous and the most important to destroy with anticancer treatments. Cancer stem cells are thought to give rise to some cells with high replicative capabilities and others with more limited replicative potential. It is not yet clear how many types of tumors have stem cells that differ from the majority of the other cells in the tumor.

 One way to identify cancer stem cells is to purify different classes of cells from a tumor based on differences in their surface markers, usually using a fluorescence-activated cell sorter (FACS, see Chapter 9). Transplantation tests, usually with mice, reveal which classes of cell have the ability to seed a new tumor and which do not. For example, a sample of a few hundred human brain tumor cells with an antigen called *CD133* on the surface is potent in starting new tumors in immunologically deprived mice, whereas a sample of many thousands of non-*CD133* tumor cells was unable to seed tumors. Similar findings have been made for human multiple myeloma; the majority of the cells (>95 percent) express a marker called *CD138*. The small population of cells that lacks *CD138* has considerably greater ability than the rest of the cells to start tumor growth. These findings suggest that identifying cancer stem cells and then targeting those cells specifically with drugs or antibodies may be a more effective cancer therapy than targeting bulk tumor cells. ■

The results with cancer stem cells highlight three important points. First, tumors are not always made up of uniform cells, even if they originated from a single initiating cell. Second, a minority of the cells may be the really dangerous ones. Third, tumor cells may grow faster or slower depending on whether they find themselves in a particular environment. Just as stem cells can be kept in a dividing, nondifferentiating state by virtue of occupying a suitable niche (see Chapter 21), tumor stem cells may behave according to their surroundings. Some neighboring cells may be more conducive to tumor cell or cancer stem cell growth than others. Thus the environment of tumor cells, called the *tumor microenvironment*, can have a dramatic impact on the ability of tumor cells to grow.

The idea that the tumor microenvironment matters extends to the importance of one of the most common environments for a tumor cell: inflammatory cells. Cancers frequently arise at sites of injury or chronic infection. Immune cells migrate to sites of injury and produce growth factors there to promote healing, and the extracellular matrix is reconstructed. All of these local tissue properties may contribute to the establishment and growth of a tumor. It is estimated that up to 20 percent of cancers are linked to chronic infection. For example, persistent *Helicobacter pylori* infection is associated with gastric cancer and mucosa-associated lymphoid

tissue (MALT) lymphoma. Infections with hepatitis B or C viruses increase the risk of hepatocellular carcinoma.

An inflammatory response not only can promote tumorigenesis, but tumor formation itself can trigger an inflammatory response. Certain oncogenes induce a transcriptional program that leads to the recruitment of immune cells, especially macrophages. Macrophages and other lymphocytes produce tumor-promoting cytokines and trigger an inflammatory response, providing cancer cells with additional growth factors and promoting blood vessel growth, which—as we will discuss next—is an essential aspect of tumor growth.

Tumor Growth Requires Formation of New Blood Vessels

Tumors, whether primary or secondary, require recruitment of new blood vessels in order to grow to a large mass. In the absence of a blood supply, a tumor can grow into a mass of about 10^6 cells, roughly a sphere 2 mm in diameter. At this point, division of cells on the outside of the tumor mass is balanced by death of those in the center from an inadequate supply of nutrients. Such tumors, unless they secrete hormones, cause few problems. However, most tumors induce the formation of new blood vessels that invade the tumor and nourish it, a process called *angiogenesis*. This complex process requires several discrete steps: degradation of the basement membrane that surrounds a nearby capillary, migration of endothelial cells lining the capillary into the tumor, division of these endothelial cells, and formation of a new basement membrane around the newly elongated capillary.

Many tumors produce growth factors that stimulate angiogenesis; other tumors somehow induce surrounding normal cells to synthesize and secrete such factors. Basic fibroblast growth factor (b-FGF), transforming growth factor α (TGF α), and vascular endothelial growth factor (VEGF), which are secreted by many tumors, all have angiogenic properties. New blood vessels nourish the growing tumor, allowing it to increase in size and thus increase the probability that additional harmful mutations will occur. The presence of an adjacent blood vessel also facilitates the process of metastasis.

In humans there are five VEGF genes and three VEGF-receptor-protein genes. VEGF expression can be induced by hypoxia, starvation of cells for oxygen that occurs when $[pO_2] < 7$ mmHg. The VEGF receptors, which are tyrosine kinases, regulate different aspects of blood vessel growth such as endothelial (blood vessel wall) cell survival and growth, cell migration, and vessel wall permeability.

The hypoxia signal is mediated by hypoxia-inducible factor (HIF-1), a transcription factor that is activated in conditions of low oxygen and then binds to and induces transcription of the VEGF gene and about 30 other genes, many of which can affect the probability of tumor growth. Among these are glycolytic enzymes such as lactate dehydrogenase; thus HIF-1 may also help tumor cells to adapt to low oxygen by turning to glycolysis rather than oxidative phosphorylation for ATP generation. HIF-1 activity is controlled in turn by an oxygen sensor composed of a prolyl hydroxylase that is

EXPERIMENTAL FIGURE 24-4 Scanning electron micrographs reveal the organizational and morphological differences between normal and transformed 3T3 cells. (a) Normal 3T3 cells are elongated and are aligned and closely packed in an orderly fashion. (b) 3T3 cells transformed by an oncogene encoded by Rous sarcoma virus are rounded and covered with small hairlike processes and bulbous

projections. The transformed cells have lost the side-by-side organization of the normal cells and grow one atop the other. These transformed cells have many of the same properties as malignant cells. Similar changes are seen in cells transfected with DNA from human cancers containing the *ras*^D oncogene. [Courtesy of L. B. Chen.]

active in normal O₂ levels but inactive when deprived of O₂. Hydroxylation of HIF-1 causes ubiquitinylation and degradation of the transcription factor, a process that is blocked when O₂ is low. Compounds that inhibit angiogenesis have excited much interest as potential therapeutic agents. However, their success in the clinic has thus far been limited.

Specific Mutations Transform Cultured Cells into Tumor Cells

The morphology and growth properties of tumor cells clearly differ from those of their normal counterparts; some of these differences are also evident when cells are cultured. That mutations cause these differences was conclusively established by transfection experiments with a line of cultured mouse fibroblasts called 3T3 cells. These cells normally grow only when attached to the plastic surface of a culture dish and are maintained at a low cell density. Because 3T3 cells stop growing when they contact other cells, they eventually form a monolayer of well-ordered cells that have stopped proliferating and are in the quiescent G₀ phase of the cell cycle (Figure 24-4a).

When DNA from human bladder cancer cells is transfected into cultured 3T3 cells, about one cell in a million incorporates a particular segment of the exogenous DNA that causes a phenotypic change. The progeny of the affected cell are more rounded and less adherent to one another and to the dish than are the normal surrounding cells, forming a three-dimensional cluster of cells (a focus) that can be recognized under the microscope (Figure 24-4b). Such cells, which continue to grow when the normal cells have become quiescent, have undergone oncogenic transformation. The transformed cells have properties similar to those of malignant tumor cells, including changes in cell morphology, ability to grow unattached to an extracellular matrix, reduced requirement for growth factors, secretion of plasminogen activator, and loss of actin microfilaments.

Figure 24-5 outlines the procedure for transforming 3T3 cells with DNA from a human bladder cancer and cloning the specific DNA segment that causes transformation. It was remarkable that a single small piece of DNA had this capability; if more than one incorporated DNA fragment had been needed to induce transformation, the experiment would have failed. Subsequent studies showed that the cloned segment included a mutant version of the cellular *ras* gene, where the glycine normally found in position 12 is replaced with a valine. This mutant was designated *ras*^D, where the D stands for “dominant.” The mutation is genetically dominant because the active protein has an effect even in the presence of the other, normal *ras* allele. Normal Ras protein, which participates in many intracellular signal transduction pathways activated by growth factors (see Chapter 16), cycles between an inactive, “off” state with bound GDP and an active, “on” state with bound GTP. The mutated Ras^D protein hydrolyzes bound GTP very slowly and therefore accumulates in the active state, sending a growth-promoting signal to the nucleus even in the absence of the hormones normally required to activate its signaling function.

The production and constitutive activation of Ras^D protein is not sufficient to cause transformation of normal cells in a primary (fresh) culture of human, rat, or mouse fibroblasts. Unlike cells in a primary culture, however, cultured 3T3 cells already carry several mutations, including loss-of-function mutations in the *p19ARF* or *p53* genes, which are regulators of the cell cycle and cell survival. These mutations allow 3T3 cells to grow for an unlimited time in culture if periodically diluted and supplied with nutrients, which normal unmutated cells cannot do (see Figure 9-1b). These immortal 3T3 cells are transformed into full-blown tumor cells only when they produce a constitutively active Ras protein or other oncoproteins. For this reason, transfection with the *ras*^D gene can transform 3T3 cells but not normal cultured primary fibroblast cells into tumor cells.

EXPERIMENTAL FIGURE 24-5 Transformation of mouse cells with DNA from a human cancer cell permits identification and molecular cloning of the *ras*^D oncogene. Addition of DNA from a human bladder cancer to a culture of mouse 3T3 cells causes about one cell in a million to divide abnormally and form a focus, or clone, of transformed cells. To clone the oncogene responsible for transformation, advantage is taken of the fact that most human genes have nearby repetitive DNA sequences called *Alu* sequences. DNA from the initial focus of transformed mouse cells is isolated, and the oncogene is separated from adventitious human DNA by secondary transfer to mouse cells. The adventitious DNA is human DNA that has no effect on cell transformation but just happened to end up in a cell that also contains the active oncogene. The total DNA from a secondary transfected mouse cell is then cloned into bacteriophage λ ; only the phage that receives human DNA hybridizes with an *Alu* probe. The hybridizing phage should contain part of or all the transforming oncogene. This expected result can be proved by showing either that the phage DNA can transform cells (if the oncogene has been completely cloned) or that the cloned piece of DNA is always present in cells transformed by DNA transfer from the original bladder cancer donor cell.

A mutant *ras* gene is found in most human colon, bladder, pancreatic, and other cancers but not in normal human DNA; thus it must arise as the result of a somatic mutation in one of the tumor progenitor cells. As we will see in Section 24.2, any gene, such as *ras*^D, that encodes a protein capable of transforming cells in culture or contributing to cancer in animals is referred to as an **oncogene**. An oncogene arises from a normal cellular gene, a proto-oncogene, such as *ras*.

A Multi-hit Model of Cancer Induction Is Supported by Several Lines of Evidence

As noted earlier and illustrated by the oncogenic transformation of 3T3 cells, multiple mutations usually are required to convert a normal body cell into a malignant one. According to this “multi-hit” model, evolutionary (or “survival of the fittest”) cancers arise by a process of clonal selection not unlike the selection of individual animals in a large population. Here is the scenario, which may or may not apply to all cancers: A mutation in one cell, perhaps a stem cell, would give it a slight growth advantage. One of the progeny cells would then undergo a second mutation that would allow its descendants to grow more uncontrollably and form a small benign tumor; a third mutation in a cell within this tumor would allow it to outgrow the others and overcome constraints imposed by the tumor microenvironment, and its progeny would form a mass of cells, each of which would have these three mutations. An additional mutation in one of these cells would allow its progeny to escape into the bloodstream and establish daughter colonies at other sites, the hallmark of metastatic cancer. This model makes two easily testable predictions.

First, all cells in a given tumor should have at least some genetic alterations in common. Systematic analysis of cells from individual human tumors supports the prediction that all the cells are derived from a single progenitor. Recall that

EXPERIMENTAL FIGURE 24-6 The incidence of human cancers increases as a function of age. The marked increase in the incidence with age is consistent with the multi-hit model of cancer induction. Note that the logarithm of annual incidence is plotted versus the logarithm of age. [From B. Vogelstein and K. Kinzler, 1993, *Trends Genet.* 9:101.]

during the fetal development of a human female each cell inactivates one of the two X chromosomes. A woman is a genetic mosaic: half her cells have one X inactivated, and the remainder have the other X inactivated. If a tumor did not arise from a single progenitor, it would be composed of a mix of cells with one or the other X inactivated. However, the opposite is observed: all the cells in a tumor taken from a woman have the same inactive X chromosome. Different tumors can be composed of cells with either the maternal or the paternal X inactive. Second, cancer incidence should increase with age because it can take decades for the required multiple mutations to occur. Assuming that the rate of mutation is roughly constant during a lifetime, then the incidence of most types of cancer would be independent of age if only one mutation were required to convert a normal cell into a malignant one. In fact, current estimates suggest 5–6 “hits,” or mutations, must accumulate as the most dangerous cancer cells emerge. As the data in Figure 24-6 show, the incidence of many types of human cancer does indeed increase drastically with age.

More direct evidence that multiple mutations are required for tumor induction comes from transgenic mice. A variety of combinations of oncogenes can cooperate in causing cancer. For example, mice have been made that carry either the mutant *ras*^{V12} dominant oncogene (one version of *ras*^D) or the *c-myc* proto-oncogene, in each case under control of a mammary-cell-specific promoter/enhancer from a retrovirus. The promoter is induced by endogenous hormone levels and tissue-specific regulators, leading to overexpression of *c-myc* or *ras*^{V12} in breast tissue. Myc protein is a transcription factor that induces expression of many genes required for the transition from the G₁ to the S phase of the cell cycle. Heightened transcription of *c-myc* mimics previously identified oncogenic mutations that turn up *c-myc* transcription, converting the proto-oncogene into an oncogene. By itself, the *c-myc* transgene causes tumors only after

EXPERIMENTAL FIGURE 24-7 The kinetics of tumor appearance in female mice carrying either one or two oncogenic transgenes shows the cooperative nature of multiple mutations in cancer induction. Each of the transgenes was driven by the mouse mammary tumor virus (MMTV) breast-specific promoter. The hormonal stimulation associated with pregnancy activates the MMTV promoter and hence the overexpression of the transgenes in mammary tissue. The graph shows the time course of tumorigenesis in mice carrying either *myc* or *ras*^{V12} transgenes as well as in the progeny of a cross of *myc* carriers with *ras*^{V12} carriers that contain both transgenes. The results clearly demonstrate the cooperative effects of multiple mutations in cancer induction. [See E. Sinn et al., 1987, *Cell* 49:465.]

100 days and then in only a few mice; clearly only a minute fraction of the mammary cells that overproduce the Myc protein actually become malignant. Similarly, production of the mutant *Ras*^{V12} protein alone causes tumors earlier but still slowly and with about 50 percent efficiency over 150 days. When the *c-myc* and *ras*^{V12} transgenes are crossed, however, such that all mammary cells overproduce both Myc and *Ras*^{V12}, tumors arise much more rapidly and all animals succumb to cancer (Figure 24-7). Such experiments emphasize the synergistic effects of multiple oncogenes. They also suggest that the long latency of tumor formation, even in the double-transgenic mice, is due to the need to acquire still more somatic mutations.

Similar cooperative effects between oncogenes can be seen in cultured cells. For example, transfection of normal fibroblasts (not immortalized 3T3 fibroblasts) with either *c-myc* or activated *ras*^D is not sufficient for oncogenic transformation, whereas when transfected together, the two genes cooperate to transform the cells. Deregulated levels of *c-myc* alone induce proliferation but also sensitize fibroblasts to apoptosis. Overexpression of activated *ras*^D alone induces cells to go into a state where they can no longer divide, which is termed *senescence*. When the two oncogenes are expressed in the same cell, these negative cellular responses are neutralized and the cells undergo transformation. While the examples mentioned are combinations of oncogenes, it is also possible to enhance cancer rates of cultured cell transformations by combining an oncogene with the loss of a tumor-suppressor gene.

Successive Oncogenic Mutations Can Be Traced in Colon Cancers

Studies on colon cancer provide the most compelling evidence to date for the *multi-hit model of cancer induction*. Surgeons can obtain fairly pure samples of many human

FIGURE 24-8 The development and metastasis of human colorectal cancer and its genetic basis. A mutation in the *APC* tumor-suppressor gene in a single epithelial cell causes the cell to divide, although surrounding cells do not, forming a mass of localized benign tumor cells, or a polyp. Subsequent mutations lead to expression of a constitutively active *Ras* protein and loss of the tumor-suppressor gene *p53*. This, together with additional yet to be identified genetic changes, generates a malignant cell. The cell continues to divide, and the progeny invade the basement membrane that surrounds the tissue. Some tumor cells spread into blood vessels that will distribute them to other sites in the body. Additional mutations permit the tumor cells to exit from the blood vessels and proliferate at distant sites; a person with such a tumor is said to have cancer. [Adapted from B. Vogelstein and K. Kinzler, 1993, *Trends Genet.* 9:101.]

cancers, but since the tumor is observed only at one time, its exact stage of progression cannot be easily determined. An exception is colon cancer, which evolves through distinct, well-characterized morphological stages. These intermediate stages—polyps, benign adenomas, and carcinomas—can be

isolated by a surgeon, allowing mutations that occur in each of the morphological stages to be identified. Numerous studies show that colon cancer arises from a series of mutations that commonly occur in a well-defined order, providing strong support for the multi-hit model (Figure 24-8).

Insight into the progression of colon cancer first came from the study of inherited predispositions to colon cancer such as familial adenomatous polyposis (FAP). Mutations in the Wnt signaling pathway have been identified in many of these syndromes, and it is now believed that deregulation of Wnt signaling results in formation of polyps (precancerous growths) on the inside of the colon wall—not just in people with inherited polyposis syndromes, but also in people afflicted with sporadic forms of colon cancer. APC (adenomatous polyposis coli) is a negative regulator of Wnt signaling, which promotes cell cycle entry by activating expression of the *c-myc* gene (see Chapter 16). The absence of functional APC protein thus leads to inappropriate production of Myc, and cells homozygous for APC mutations proliferate at a rate higher than normal and form polyps. Loss-of-function mutations in the APC gene are the most frequent mutations found in early stages of colon cancer. Most of the cells in a polyp contain the same one or two mutations in the APC gene that result in its loss or inactivation, indicating that they are clones of the cell in which the original mutation occurred. Thus APC is a tumor-suppressor gene, and both alleles of the APC gene must carry an inactivating mutation for polyps to form because cells with one wild-type APC gene express enough APC protein to function normally.

If one of the cells in a polyp undergoes another mutation, this time an activating mutation of the *ras* gene, its progeny divide in an even more uncontrolled fashion, forming a larger adenoma. Inactivation of the *p53* gene follows and results in the gradual loss of normal regulation and the consequent formation of a malignant carcinoma (see Figure 24-8). The *p53* protein is a tumor suppressor that halts progression through the cell cycle in response to DNA damage. While the three “hits” listed here are certainly crucial parts of the picture, there are likely to be additional contributing genetic events. Not every colon cancer, however, acquires all the later mutations or acquires them in the order depicted in Figure 24-8. Thus different combinations of mutations may result in the same phenotype.

DNA from different human colon carcinomas generally contains mutations in all three genes—loss-of-function mutations in the tumor suppressors APC, and *p53* and an activating (gain-of-function) mutation in the dominant oncogene *K-ras* (one of the *ras* family of genes)—establishing that multiple mutations in the same cell are needed for the cancer to form. Some of these mutations appear to confer growth advantages at an early stage of tumor development, whereas other mutations promote the later stages, including invasion and metastasis, which are required for the malignant phenotype. The number of mutations needed for colon cancer progression may at first seem surprising, seemingly an effective barrier to tumorigenesis. Our genomes, however, are under constant assault. Recent estimates indicate that sporadically arising polyps have about 11,000 genetic alterations in each cell, though very likely only a few of these are relevant to oncogenesis. Genetic instability is a hallmark of cancer cells. This genomic instability promotes further tumor evolution, allowing for the

accelerated creation of tumor cells with increased self-reliance and/or the ability to metastasize.

Colon carcinoma provides an excellent example of the multi-hit model of cancer. The degree to which this model applies to cancer generally is only now being learned, but it is clear that many types of cancer involve multiple mutations.

Cancer Cells Differ from Normal Cells in Fundamental Ways

Cancer cells can often be distinguished from normal cells by microscopic examination. They are usually less well differentiated than normal cells or benign tumor cells. In a specific tissue, malignant cells usually exhibit the characteristics of rapidly growing cells, that is, a high nucleus-to-cytoplasm ratio, prominent nucleoli, an increased frequency of mitotic cells, and relatively little specialized structure. Normal cells stop growing when they contact other cells, eventually forming a monolayer of well-ordered cells (see Figure 24-4a). Transformed cells are less adherent, forming a three-dimensional cluster of cells (a focus) that can be recognized under the microscope (see Figure 24-4b).

Tumor cells not only differ from normal cells in their appearance, but their entire energy metabolism is rewired. Normal differentiated cells rely on mitochondrial oxidative phosphorylation to satisfy their energy needs. Cells metabolize glucose to carbon dioxide by oxidation of pyruvate through the tricarboxylic acid (TCA) cycle in the mitochondria (see Chapter 12). Only under anaerobic conditions do cells undergo anaerobic glycolysis and produce large amounts of lactate. In contrast to normal cells, most cancer cells rely on glycolysis for energy production irrespective of whether oxygen levels are high or low, producing large amounts of lactate (Figure 24-9). The use of glycolysis to produce energy even in the presence of oxygen, called aerobic glycolysis, was first discovered in cancer cells by the cell biologist Otto Warburg and is therefore called the Warburg effect.

The metabolism of glucose to lactate generates only 2 ATP molecules per molecule of glucose, while oxidative phosphorylation generates up to 36 molecules of ATP per molecule of glucose. It is unclear why cancer cells utilize this inefficient way to generate energy, but some of the molecular differences between normal differentiated cells and cancer cells may provide the answer. Whereas differentiated cells express the M1 isoform of pyruvate kinase (PK-M1), all cancer cells switch to expression of the M2 isoform, which is normally expressed only during embryonic development. PK-M2 is activated by tyrosine kinase signaling and results in conversion of pyruvate into lactate rather than feeding into the TCA cycle.

Perhaps the most striking feature of tumor cells is that their entire genetic makeup differs dramatically from that of normal cells. Characteristic of nearly all tumor cells is **aneuploidy**, the presence of an aberrant number of chromosomes—generally too many.

Several mechanisms have been identified that lead to aneuploidy. As discussed in Chapter 19, the DNA replication

FIGURE 24-9 Energy production in cancer cells by aerobic glycolysis. In the presence of oxygen, nonproliferating (differentiated) cells metabolize glucose into pyruvate via glycolysis. Pyruvate is then transported into mitochondria, where it is fed into the TCA cycle. Oxygen is required as the final electron acceptor during oxidative phosphorylation. Thus when oxygen is limiting, cells metabolize pyruvate into lactate, allowing glycolysis to continue by cycling NADH back to NAD⁺. Cancer cells and proliferating cells convert most glucose to lactate regardless of whether oxygen is present or not. The production of lactate in the presence of oxygen is called aerobic glycolysis. [Adapted from Vander Heiden et al., 2009, *Science* 324:1029.]

checkpoint normally prevents entry into mitosis unless all chromosomes have completely replicated their DNA. The spindle assembly checkpoint prevents entry into anaphase unless all the replicated chromosomes attach properly to the spindle apparatus, and the spindle position checkpoint prevents exit from mitosis and cytokinesis if the chromosomes segregate improperly. A failure in the DNA damage and spindle assembly checkpoints causes chromosomal abnormalities and mis-segregation, respectively, leading to aneuploidy. Defects in the spindle position checkpoint cause the formation of tetraploid cells, which then through chromosome losses can also become aneuploid. The exact role of aneuploidy in tumorigenesis is being debated, but it is clear that aneuploidy causes cancer. Mutations that induce genomic instability lead to cancer in mice. Human syndromes such as mosaic variegated aneuploidy (MVA) that cause increased chromosome mis-segregation also predispose patients to certain cancers, including Wilms's tumor and rhabdomyosarcoma.

DNA Microarray Analysis of Expression Patterns Can Reveal Subtle Differences Between Tumor Cells

Traditionally the properties of tumor and normal cells have been assessed by staining and microscopy. The prognosis for many tumors could be determined, within certain limits, from their histology. However, the appearance of cells alone has limited information content, and better ways to discern the properties of cells are desirable both to understand tumorigenesis and to arrive at meaningful and accurate decisions about prognosis and therapy.

As we have seen, genetic studies can identify the single initiating mutation or series of mutations that cause transformation of normal cells into tumor cells, as in the case of colon cancer. After these initial events, however, the cells of a tumor

undergo a cascade of changes reflecting the interplay between the initiating events and signals from outside. As a result, tumor cells can become quite different, even if they arise from the same initiating mutation or mutations. Although these differences may not be recognized from the appearance of cells, they can be detected from the cells' patterns of gene expression. DNA microarray analysis can determine the expression of tens of thousands of genes simultaneously, permitting complex phenotypes to be defined at the molecular genetic level. (See Figures 5-29 and 5-30 for an explanation of this technique.)

The advent of DNA microarray and large-scale sequencing technology is allowing more detailed examination of tumor properties. Not surprisingly, primary tumors can often be distinguishable from metastatic tumors by the pattern of gene expression. Microarray analysis is now also routinely used to determine patient outcome and the best course of treatment for many types of cancers.

 Patients affected by breast cancer have markedly different treatment responses and highly variable outcomes. Chemotherapy and hormonal therapies reduce the risk of metastases by approximately 30 percent, but 70–80 percent of these patients would have survived without the treatment. Determining which patient should receive chemotherapy to prevent metastases is thus a critical question. Microarray analyses have provided a means to make this decision. Researchers analyzed the gene expression profile of breast cancers that had not yet spread to neighboring lymph nodes (non-metastatic breast cancers). They identified 70 genes whose expression predicts the likelihood of metastasis with more than 90 percent accuracy (Figure 24-10). This “classifier” gene expression signature of poor prognosis contained genes involved in cell cycle progression, invasion, and angiogenesis, providing a biological basis for why metastasis was more likely in this patient group than in the patient group that lacked this gene expression signature. Based on these gene expression classifiers, it may now be easier to determine which patients will benefit from aggressive chemotherapies and which will not need this aggressive treatment. Similar analyses of the gene expression patterns of other tumors are likely to improve classification and diagnosis, allowing informed decisions about treatments, and also to provide insights into the properties of tumor cells. ■

EXPERIMENTAL FIGURE 24-10 Differences in gene-expression patterns determined by DNA microarray analysis can predict metastatic behavior of breast cancers. Samples of mRNA were extracted from 78 breast cancer patients (age 55 and younger) that carried sporadic breast tumors that had not yet spread to neighboring lymph nodes. DNA microarray analysis of the extracted RNA determined the transcription levels of about 25,000 genes in each of the 78 experimental samples. (See Figures 5-29 and 5-30 for a description of microarray analysis.) A prognostic gene expression signature of 70 genes was then determined. First all genes were identified that were up-regulated in more than three of the 78 tumors. The correlation coefficient of the expression for each gene with disease outcome (patients who were metastasis free after five years versus patients who developed distant metastases within five years) was then calculated, and 231 genes were found to be significantly associated with disease outcome. Genes were further selected by eliminating genes with lower predictive power until a set of genes was determined whose expression patterns classified poor-prognosis patients with more than 90 percent accuracy. The classifier gene expression signature of these 70 genes is shown. In the cluster diagram, each row represents one tumor, and each vertical column contains data for a single gene of the 70-gene cluster. An intense red color indicates a high level of transcription of that gene; intense green indicates the opposite. The genes were grouped according to their similar patterns of hybridization. Patients above the yellow line have a good prognosis signature; below the yellow line the prognosis signature is poor. The metastasis status of each patient is shown to the right. White indicates patients developed distant metastases within five years after the initial diagnosis; black indicates that patients were disease free for at least five years. [From L. J. van't Veer, 2002, *Nature* 415:530.]

KEY CONCEPTS of Section 24.1

Tumor Cells and the Onset of Cancer

- Cancer is a fundamental aberration in cellular behavior, touching on many aspects of molecular cell biology. Most cell types of the body can give rise to malignant tumor (cancer) cells.
- Cancer cells can multiply in the absence of at least some of the growth-promoting factors required for proliferation of normal cells and are resistant to signals that normally program cell death (apoptosis).

- Most oncogenic mutations occur in somatic cells and are not carried in the germ-line DNA.
- Cancer cells sometimes invade surrounding tissues, often breaking through the basement membranes that define the boundaries of tissues and spreading through the body to establish secondary areas of growth, a process called *metastasis*. Metastatic tumor cells acquire migratory properties in a process called the epithelial-to-mesenchymal transition.
- Cancer cells may arise from stem cells and often arise from proliferating cells. Cancer cells bear more resemblance to dividing precursor cells than to more mature differentiated cell types.
- Both primary and secondary tumors require angiogenesis, the formation of new blood vessels, in order to grow to a large mass.
- The multi-hit model, which proposes that multiple mutations are needed to cause cancer, is consistent with the genetic homogeneity of cells from a given tumor, the observed increase in the incidence of human cancers with advancing age, and the cooperative effect of oncogenic transgenes and tumor-suppressor gene mutations on tumor formation in mice.
- Colon cancer develops through distinct morphological stages that commonly are associated with mutations in specific tumor-suppressor genes and proto-oncogenes.
- Cancer cells differ from normal cells in fundamental ways. Particularly striking is the rewiring of energy metabolism toward glycolysis, a process known as the Warburg effect.
- Most human tumor cells are aneuploid, containing an abnormal number of chromosomes (usually too many). Failure of cell cycle checkpoints that normally detect unreplicated DNA, improper spindle assembly, or mis-segregation of chromosomes permits aneuploid cells to arise.
- DNA microarray analysis can identify differences in gene expression between types of tumor cells that are indistinguishable by traditional criteria and can be used to predict patient outcome.

24.2 The Genetic Basis of Cancer

As we have noted, mutations in three broad classes of genes—proto-oncogenes (e.g., *ras*), tumor-suppressor genes (e.g., *APC*), and caretaker genes—play key roles in cancer induction. These genes encode many kinds of proteins that help control cell growth and proliferation (Figure 24-11). Virtually all human tumors have inactivating mutations in genes whose products normally act at various cell cycle checkpoints to stop a cell's progress through the cell cycle if a previous step has occurred incorrectly or if DNA has been damaged. For example, most cancers have inactivating mutations in the genes coding for one or more proteins that normally restrict progression through the G₁ stage of the cell cycle or activating mutations in genes coding for proteins that drive the cells through the cell cycle. Likewise,

FIGURE 24-11 Seven types of proteins that participate in controlling cell growth and proliferation. Cancer can result from expression of mutant forms of these proteins. Mutations changing the structure or expression of proteins that normally promote cell growth generally give rise to dominantly active oncogenes. Many, but not all, extracellular signaling molecules (I), signal receptors (II), signal transduction proteins (III), and transcription factors (IV) are in this category. Cell-cycle-control proteins (V) that function to restrain cell proliferation and DNA-repair proteins (VI) are encoded by tumor-suppressor genes. Mutations in these genes act recessively, greatly increasing the probability that the mutant cells will become tumor cells or that mutations will occur in other classes. Apoptotic proteins (VII) include tumor suppressors that promote apoptosis and oncoproteins that promote cell survival. Virus-encoded proteins that activate signal receptors (Ia) also can induce cancer.

a constitutively active Ras or other activated signal transduction protein is found in several kinds of human tumors that have different origins. Thus malignancy and the intricate processes for controlling the cell cycle discussed in Chapter 19 are two faces of the same coin. In the series of events leading to growth of a tumor, oncogenes combine with tumor-suppressor mutations to give rise to the full spectrum of tumor-cell properties described in the previous section.

In this section, we consider the general types of mutations that are oncogenic and see how certain viruses can cause cancer. We also explain why some inherited mutations increase the risk for particular cancers.

Gain-of-Function Mutations Convert Proto-oncogenes into Oncogenes

Recall that an oncogene is any gene that encodes a protein able to transform cells in culture, usually in combination with other cell alterations, or to induce cancer in animals. Of the many known oncogenes, all but a few are derived from normal cellular genes (i.e., proto-oncogenes) whose wild-type products promote cell proliferation or other features important for cancer. For example, the *ras* gene discussed previously is a proto-oncogene that encodes an intracellular signal transduction protein that

promotes controlled progression through the cell cycle; the mutant *ras^D* gene derived from *ras* is an oncogene whose encoded protein provides an excessive or uncontrolled growth-promoting signal. Other proto-oncogenes encode growth-promoting signaling molecules and their receptors, anti-apoptotic (cell-survival) proteins, and some transcription factors.

Conversion, or activation, of a proto-oncogene into an oncogene generally involves a *gain-of-function* mutation. At least four mechanisms can produce oncogenes from the corresponding proto-oncogenes:

1. *Point mutation* (i.e., change in a single base pair) in a proto-oncogene that results in a hyperactive or constitutively active protein product
2. *Chromosomal translocation* that fuses two genes together to produce a hybrid gene encoding a chimeric protein whose activity, unlike that of the parent proteins, often is constitutive
3. *Chromosomal translocation* that brings a growth regulatory gene under the control of a different promoter that causes inappropriate expression of the gene
4. *Amplification* (i.e., abnormal DNA replication) of a DNA segment including a proto-oncogene, so that numerous copies exist, leading to overproduction of the encoded protein

An oncogene formed by either of the first two mechanisms encodes an “oncoprotein” that differs from the normal protein encoded by the corresponding proto-oncogene. In contrast, the other two mechanisms generate oncogenes whose protein products are identical with the normal proteins; their oncogenic effect is due to production at higher-than-normal levels or in cells where they normally are not produced.

The localized amplification of DNA to produce as many as 100 copies of a given region (usually a region spanning hundreds of kilobases) is a common genetic change seen in tumors. Normally such an event would be repaired or the cell would stop cycling owing to checkpoint control, so such lesions imply a DNA-repair (caretaker) defect of some kind. This anomaly may take either of two forms: the duplicated DNA may be tandemly organized at a single site on a chromosome, or it may exist as small, independent mini-chromosome-like structures. The former case leads to a homogeneously staining region (HSR) that is visible in the light microscope at the site of the amplification; the latter case causes extra “minute” chromosomes, separate from the normal chromosomes that pepper a stained chromosomal preparation (Figure 24-12).

However they arise, the gain-of-function mutations that convert proto-oncogenes to oncogenes are genetically dominant; that is, mutation in only one of the two alleles is sufficient for induction of cancer. See Table 24-1 for a comparison of different classes of cancer-related genes.

 Gene amplification may involve a small number of genes, such as the *N-myc* gene and its neighbor *DDX1*, which

are amplified in neuroblastoma, or a chromosome region containing many genes. It can be difficult to determine which genes are amplified, a first step in determining which genes contribute to tumor formation. DNA microarrays or deep sequencing offer a powerful approach for finding amplified regions of chromosomes. Rather than look at gene expression, the application of microarrays or quantitative sequence analysis involves looking for abnormally abundant DNA sequences. In the microarray approach, genomic DNA from cancer cells is used to probe arrays containing fragments of genomic DNA, and spots with amplified DNA give stronger signals than control spots. In the deep-sequencing approach, the genome is broken into small fragments and sequenced. The frequency with which a particular region of the genome is sequenced provides a quantitative assessment of the copy number at a particular locus. Among the amplified genes, the strongest candidates for the relevant ones can be identified by also measuring gene expression. A breast carcinoma cell line, with four known amplified chromosome regions, was screened for amplified genes, and the expression levels of those genes were also studied on microarrays. Fifty genes were found to be amplified, but only five were also highly expressed. These five were better candidates for being new oncogenes since amplified genes that are not highly expressed are less likely to contribute to tumor growth. As microarray and whole-genome sequencing approaches become cheaper, it is possible that tumors from individual patients will routinely be analyzed in this manner to determine which oncogenic mutations underlie the tumor. Treatment could then be tailored specifically to the patient's tumor. ■

EXPERIMENTAL FIGURE 24-12 DNA amplifications in stained chromosomes take two forms, visible under the light microscope.

(a) Homogeneously staining regions (HSRs) in a human chromosome from a neuroblastoma cell. The chromosomes are uniformly stained with a blue dye so that all can be seen. Specific DNA sequences were detected using fluorescent in situ hybridization (FISH) in which fluorescently labeled DNA clones are hybridized to denatured DNA in the chromosomes. The chromosome 4 pair is marked (red) by in situ hybridization with a large DNA clone containing the *N-myc* oncogene.

On one of the chromosome 4's an HSR is visible (green) after staining for a sequence enriched in the HSR. (b) Optical sections through nuclei from a human neuroblastoma cell that contain so-called double-minute chromosomes. The normal chromosomes are the green and blue structures; the double-minute chromosomes are the many small red dots. Arrows indicate double minutes associated with the surface or interior of the normal chromosomes. [From I. Solovei et al., 2000, *Genes Chromosomes Cancer* 29:297–308, figs. 4 and 17.]

TABLE 24-1 Classes of Genes Implicated in the Onset of Cancer

	Normal Function of Genes	Examples of Gene Products	Effect of Mutation	Genetic Properties of Mutant Gene	Origin of Mutations
Proto-oncogenes	Promote cell survival or proliferation	Anti-apoptotic proteins, components of signaling and signal transduction pathways that result in proliferation, transcription factors	Gain-of-function mutations allow unregulated cell proliferation and survival	Mutations are genetically dominant	Arise by point mutation, chromosomal translocation, amplification
Tumor-suppressor genes	Inhibit cell survival or proliferation	Apoptosis-promoting proteins, inhibitors of cell-cycle progression, checkpoint-control proteins that assess DNA/chromosomal damage, components of signal pathways that restrain cell proliferation	Loss-of-function mutations allow unregulated cell proliferation and survival	Mutations are genetically recessive	Arise by deletion, point mutation, methylation
Caretaker genes	Repair or prevent DNA damage	DNA-repair enzymes	Loss-of-function mutations allow mutations to accumulate	Mutations are genetically recessive	Arise by deletion, point mutation, methylation

Cancer-Causing Viruses Contain Oncogenes or Activate Cellular Proto-oncogenes

Pioneering studies by Peyton Rous beginning in 1911 led to the initial recognition that a virus could cause cancer when injected into a suitable host animal. Many years later, molecular biologists showed that Rous sarcoma virus (RSV) is a **retrovirus** whose RNA genome is reverse-transcribed into DNA, which is incorporated into the host-cell genome (see Figure 4-49). In addition to the “normal” genes present in all retroviruses, oncogenic transforming viruses such as RSV contain an oncogene: in the case of RSV, the *v-src* gene. Subsequent studies with mutant forms of RSV demonstrated that only the *v-src* gene, not the other viral genes, was required for cancer induction.

In the late 1970s, scientists were surprised to find that normal cells from chickens and other species contain a gene that is closely related to the RSV *v-src* gene. This normal cellular gene, a proto-oncogene, commonly is distinguished from the viral gene by the prefix “c” (*c-src*). RSV and other acutely transforming viruses are thought to have arisen by incorporating, or transducing, a normal cellular proto-oncogene into their genome. Subsequent mutation in the transduced gene then converted it into a dominantly acting oncogene, which can induce cell transformation even in the presence of the normal *c-src* proto-oncogene. Such viruses are called *transducing retroviruses* because their genomes contain an oncogene derived from a transduced cellular proto-oncogene. When this was first discovered, it was startling to find that these dangerous viruses were turning the animal’s own genes against them.

Because its genome carries the potent *v-src* oncogene, the transducing RSV induces tumors within days. In contrast, most oncogenic retroviruses induce cancer only after a period of months or years. The genomes of these *slow-acting retroviruses*, which are weakly transforming, differ from those of transducing viruses in one crucial respect: they lack an oncogene. All slow-acting, or “long-latency,” retroviruses appear to cause cancer by integrating into the host-cell DNA near a cellular proto-oncogene and activating its expression. The long terminal repeat (LTR) sequences in integrated retroviral DNA can act as an enhancer or promoter for a nearby cellular gene, thereby stimulating its transcription. For example, in the cells from tumors caused by avian leukosis virus (ALV), the retroviral DNA is inserted near the *c-myc* gene. These cells overproduce c-Myc protein; as noted earlier, overproduction of c-Myc causes abnormally rapid proliferation of cells. Slow-acting viruses act slowly for two reasons: integration near a cellular proto-oncogene (e.g., *c-myc*) is a random, rare event, and additional mutations have to occur before a full-fledged tumor becomes evident.

In natural bird and mouse populations, slow-acting retroviruses are much more common than oncogene-containing retroviruses such as Rous sarcoma virus. Thus insertional proto-oncogene activation is probably the major mechanism by which retroviruses cause cancer. Although the only retrovirus known to cause human tumors is human T-cell leukemia/lymphoma virus (HTLV), the huge investment in studying retroviruses as a model for human cancer paid off both in the discovery of cellular oncogenes and in the

sophisticated understanding of retroviruses, which later accelerated progress on the HIV virus that causes AIDS.

A few DNA viruses also are oncogenic. Unlike most DNA viruses that infect animal cells (see Chapter 4), oncogenic DNA viruses integrate their viral DNA into the host-cell genome. The viral DNA contains one or more oncogenes, which permanently transform infected cells. For example, many warts and other benign tumors of epithelial cells are caused by the DNA-containing human papillomaviruses (HPV). A medically much more serious outcome of HPV infection is cervical cancer, the third most common type of cancer in women after lung and breast cancer. The Pap smear, which is used to sample the cervical tissue and screen for possible cancers, is thought to have reduced the death rate by about 70 percent. However, thousands of people still die from cervical cancer each year, and some of these deaths would have been prevented had screening been done. Fortunately, not all HPV infections lead to cancer. We will learn more about HPV oncoproteins later in the chapter.

Unlike retroviral oncogenes, which are derived from normal cellular genes and have no function for the virus except to allow their proliferation in tumors, the known oncogenes of DNA viruses are integral parts of the viral genome and are required for viral replication. As discussed later, the oncoproteins expressed from integrated viral DNA in infected cells act in various ways to stimulate cell growth and proliferation.

Loss-of-Function Mutations in Tumor-Suppressor Genes Are Oncogenic

Tumor-suppressor genes generally encode proteins that in one way or another inhibit cell proliferation. *Loss-of-function* mutations in one or more of these “brakes” contribute to the development of many cancers. Prominent among the classes of proteins encoded by tumor-suppressor genes are these five:

1. Intracellular proteins that regulate, or inhibit, entry into the cell cycle (e.g., p16 and Rb for G₁)
2. Receptors or signal transducers for secreted hormones or developmental signals that inhibit cell proliferation (e.g., TGF β and the hedgehog receptor Patched)
3. Checkpoint-control proteins that arrest the cell cycle if DNA is damaged or if the chromosome segregation apparatus is abnormal (e.g., p53)
4. Proteins that promote apoptosis
5. Enzymes that participate in DNA repair

Since generally one copy of a tumor-suppressor gene suffices to control cell proliferation, *both* alleles of a tumor-suppressor gene must be lost or inactivated in order to promote tumor development. Thus oncogenic loss-of-function mutations in tumor-suppressor genes are often genetically *recessive* (see Table 24-1). In this context “recessive” means that if there is even one working gene, producing about half the usual amount of protein product, tumor formation will be prevented. With some genes, half the amount of product is not enough, in which case the loss of just one of the two genes can lead to cancer. This kind of gene

is *haplo-insufficient*. The loss of one copy of the gene is decisive for the final phenotype, so this type of mutation is dominant. It is useful to remember, then, two processes by which cancer genes can be dominant: (1) loss of one copy of a haplo-insufficient tumor-suppressor gene, resulting in insufficient product to control growth, and (2) activation of a gene or protein that causes growth even in the presence of one normal allele, that is, a dominant oncogene (as was described in the previous section). In many cancers, tumor-suppressor genes have deletions or point mutations that prevent production of any protein or lead to production of a nonfunctional protein. Another mechanism for inactivating tumor-suppressor genes is methylation of cytosine residues in the promoter or other control elements, which inhibits their transcription. Such methylation is commonly found in nontranscribed regions of DNA (see Chapter 7).

Inherited Mutations in Tumor-Suppressor Genes Increase Cancer Risk

Individuals with inherited mutations in tumor-suppressor genes have a hereditary predisposition for certain cancers. Such individuals generally inherit a germ-line mutation in one allele of the gene; somatic mutation of the second allele facilitates tumor progression. A classic case is retinoblastoma, which is caused by loss of function of *RB*, the first tumor-suppressor gene to be identified. As we discuss later, the protein encoded by *RB* regulates cell cycle entry.

Hereditary versus Sporadic Retinoblastoma Children with hereditary retinoblastoma inherit a single defective copy of the *RB* gene, sometimes seen as a small deletion on one of the two copies of chromosome 13. The children develop several retinal tumors early in life and generally in both eyes. The deletion or mutation of the normal *RB* gene on the other chromosome is an essential step in tumor formation, giving rise to a cell that produces no functional Rb protein (Figure 24-13a). Individuals with sporadic retinoblastoma, in contrast, inherit two normal *RB* alleles, each of which has undergone a loss-of-function somatic mutation in a single retinal cell (Figure 24-13b). Because losing two copies of the *RB* gene is far less likely than losing one, sporadic retinoblastoma is rare and usually affects only one eye.

If retinal tumors are removed before they become malignant, children with hereditary retinoblastoma often survive until adulthood and produce children but are at an increased risk of developing other types of tumors later in life. Because their germ cells contain one normal and one mutant *RB* allele, these individuals will, on average, pass on the mutant allele to half their children and the normal allele to the other half. Children who inherit the normal allele are normal if their other parent has two normal *RB* alleles. However, those who inherit the mutant allele have the same enhanced predisposition to develop retinal tumors as their affected parent, even though they inherit a normal *RB* allele from their other, normal parent. Thus the *tendency* to develop retinoblastoma is inherited as a dominant trait: one mutant copy is sufficient to predispose a person to develop the cancer.

(a) Hereditary retinoblastoma

(b) Sporadic retinoblastoma

FIGURE 24-13 Role of spontaneous somatic mutation in retinoblastoma. This disease is marked by retinal tumors that arise from cells carrying two mutant RB^- alleles. (a) In hereditary (familial) retinoblastoma, a child inherits a normal RB^+ allele from one parent and a mutant RB^- allele from the other parent. A single mutation in a heterozygous somatic retinal cell that inactivates the normal allele will produce a cell lacking any Rb gene function due to two mutations. (b) In sporadic retinoblastoma, a child inherits two normal RB^+ alleles. Two separate somatic mutations in a particular retinal cell or its progeny are required to produce a homozygous RB^-/RB^- cell.

As we will see shortly, many human tumors (not just retinal tumors) contain mutant RB alleles or mutations affecting other components of the same pathway; most of these arise as the result of somatic mutations. Although the hereditary retinoblastoma cases number about 100 per year in the United States, about 100,000 other cancer cases each year involve RB mutations acquired postconception.

Inherited Forms of Colon and Breast Cancer Similar hereditary predisposition for other cancers has been associated with inherited mutations in other tumor-suppressor genes. For example, individuals who inherit a germ-line mutation in one APC allele develop thousands of precancerous intestinal polyps (see Figure 24-8). Since there is a high probability that one or more of these polyps will progress to malignancy, such individuals have a greatly increased risk for developing colon cancer before the age of 50. Screening for polyps by colonoscopy is a good idea for people 50 or older, even when no APC mutation is known to be present. Likewise, women who inherit one mutant allele of $BRCA-1$, another tumor-suppressor gene, have a 60 percent probability of developing breast cancer by age 50, whereas those who inherit two normal $BRCA-1$ alleles have a 2 percent probability of doing so. Heterozygous $BRCA-1$ mutations also increase the lifetime risk of ovarian cancer from 2 percent to 15–40 percent. $BRCA-1$ protein is involved

in repairing radiation-induced DNA damage. In women with hereditary breast cancer, loss of the second $BRCA-1$ allele, together with other mutations, is required for a normal breast duct cell to become malignant. However, $BRCA-1$ generally is not mutated in sporadic, noninherited breast cancer.

Loss of Heterozygosity Clearly, then, we can inherit a propensity for cancer by receiving a damaged allele of a tumor-suppressor gene from one of our parents; that is, we are heterozygous for the mutation. That in itself typically will not cause cancer; since the remaining normal allele prevents aberrant growth, the cancer is recessive. As we have seen, subsequent loss or inactivation of the normal allele in a somatic cell, referred to as *loss of heterozygosity* (LOH), is usually how a cancer develops. One mechanism for LOH involves mis-segregation of the chromosomes bearing the affected tumor-suppressor gene during mitosis (Figure 24-14a). This process, also referred to as *nondisjunction*, is caused by failure of the spindle assembly checkpoint, which normally prevents a metaphase cell with an abnormal mitotic spindle from completing mitosis (see Figure 19-35). Another common mechanism for LOH is mitotic recombination between a chromatid bearing the wild-type allele and a homologous chromatid bearing a mutant allele. As illustrated in Figure 24-14b, subsequent chromosome segregation can generate a daughter cell that is homozygous for the mutant tumor-suppressor allele. A third mechanism is the deletion or mutation of the normal copy of the tumor-suppressor gene; such a deletion can encompass a large chromosomal region and need not be a precise deletion of just the tumor-suppressor gene.

Estimates vary, but hereditary cancers, that is, cancers that arise due in part to an inherited version of a gene, are thought to constitute about 10 percent of human cancers. Further work tracing contributions of human genes seems likely to increase the percentage. It is important to remember, however, that the inherited germ-line mutation alone is not sufficient to cause tumor development. In all cases, not only must the inherited normal tumor-suppressor allele be lost or inactivated, but mutations affecting other genes also are necessary for cancer to develop. Thus a person with a recessive tumor-suppressor gene mutation can be exceptionally susceptible to environmental mutagens such as radiation.

Epigenetic Changes Can Contribute to Tumorigenesis

We have seen how mutations can undermine growth control by inactivating tumor-suppressor genes. However, these types of genes can also be silenced by repressive chromatin structures. In recent years the importance of *chromatin-remodeling complexes*, such as the SWI/SNF complex, in transcriptional control has become increasingly clear. These large and diverse multiprotein complexes have at their core an ATP-dependent helicase and often control histone modification and chromatin remodeling (see Chapter 7). SWI/SNF complexes, for example, cause changes in the positions or structures of nucleosomes, making genes accessible or inaccessible

(a) Mis-segregation

(b) Mitotic recombination

FIGURE 24-14 Two mechanisms for loss of heterozygosity (LOH) of tumor-suppressor genes.

A cell containing one normal and one mutant allele of a tumor-suppressor gene is generally phenotypically normal. (a) If formation of the mitotic spindle is defective, then the duplicated chromosomes bearing the normal and mutant alleles may segregate in an aberrant 3:1 ratio. A daughter cell that receives three chromosomes of a type can lose one, restoring the normal $2n$ chromosome number. Sometimes the resultant cell will contain one normal and

one mutant allele, but sometimes it will be homozygous for the mutant allele. Note that such aneuploidy (abnormal chromosome constitution) is generally damaging or lethal to relatively undifferentiated cells that have to develop into the many complex structures of an organism but can often be tolerated in clones of cells that have limited fates and duties. (b) Mitotic recombination between a chromosome with a wild-type and a mutant allele, followed by chromosome segregation, can produce a cell that contains two copies of the mutant allele.

to DNA-binding proteins that control transcription. If a gene is normally activated or repressed by SWI/SNF-mediated chromatin changes, mutations in the genes encoding the SWI or SNF proteins will cause changes in expression of the target gene. Studies with transgenic mice suggest that SWI/SNF plays a role in repressing the *E2F* genes, thereby inhibiting progression through the cell cycle. Thus loss of SWI/SNF function, just like loss of Rb function, can lead to overgrowth and perhaps cancer. Indeed, in mice, Rb protein recruits SWI/SNF proteins to repress transcription of the *E2F* gene. Rb represses genes via this effect on E2F and by recruitment of histone deacetylases and histone methyltransferases.

Recent evidence from humans and mice has strongly implicated the *SNF5* gene in cancer. *Snf5* is a core member of the SWI/SNF complex. In humans, inactivating somatic *SNF5* mu-

tations causes rhabdoid tumors, which most commonly form in the kidney, and an inherited (familial) disposition to form brain and other tumors. In mice, 15–30 percent of *snf5*⁻/*snf5*⁺ heterozygotes develop rhabdoid tumors, and in all cases the tumor cells have lost the remaining functional allele. Since nothing was known of the mechanism involved, microarray studies were used to discover regulatory changes in the tumors. These studies showed the gene-expression similarity of mouse and human tumors and that the loss of *SNF5* leads to heightened expression of cell cycle genes, including many regulated by E2F. With chromatin-remodeling complexes involved in so many aspects of transcriptional control, it is expected that SWI/SNF and similar complexes will be linked to many cancers. In humans, mutations in *Brg1*, which encodes the SWI/SNF catalytic subunit, have been found in prostate, lung, and breast tumors.

KEY CONCEPTS of Section 24.2

The Genetic Basis of Cancer

- Dominant gain-of-function mutations in proto-oncogenes and recessive loss-of-function mutations in tumor-suppressor genes are oncogenic.
- Among the proteins encoded by proto-oncogenes are growth-promoting signaling proteins and their receptors, signal transduction proteins, transcription factors, and apoptotic proteins (see Figure 24-11).
- An activating mutation of one of the two alleles of a proto-oncogene converts it to an oncogene. This can occur by point mutation, gene amplification, gene translocation, or overexpression.
- The first human oncogene to be identified encodes a constitutively active form of Ras, a signal transduction protein. This oncogene was isolated from a human bladder carcinoma (see Figure 24-5).
- Tumor-suppressor genes encode proteins that directly or indirectly interfere with progression through the cell cycle, such as checkpoint-control proteins that arrest the cell cycle in response to cell cycle defects, components of growth-inhibiting signaling pathways, pro-apoptotic proteins, regulators of kinase activities, and DNA-repair enzymes.
- The first tumor-suppressor gene to be recognized, *RB*, is mutated in retinoblastoma and many other tumors; some component of the RB pathway is altered in most tumors.
- Inheritance of a single mutant allele of *RB* greatly increases the probability that a specific kind of cancer will develop, as is the case for many other tumor-suppressor genes (e.g., *APC* and *BRCA-1*).
- In individuals born heterozygous for a tumor-suppressor gene, a somatic cell can undergo loss of heterozygosity (LOH) by mitotic recombination, chromosome mis-segregation, mutation, gene silencing, or deletion (see Figure 24-14).
- Mutations in caretaker genes are genetically recessive since having even one functional copy is usually sufficient to prevent serious DNA damage. However, a single copy leaves the carrier subject to possible LOH.
- Mutations affecting chromatin-modifying factors that participate in transcriptional control, such as the SWI/SNF chromatin-remodeling complex, are associated with a variety of tumors.

24.3 Cancer and Misregulation of Growth Regulatory Pathways

In this section, we will examine in more detail how the deregulation of growth-promoting and growth-inhibitory signaling pathways contributes to tumorigenesis. We will first

discuss how the use of mouse models of human cancers has helped shape our understanding of the process of carcinogenesis. We will then examine in more detail how mutations that result in the unregulated, constitutive activity of certain proteins or in their overproduction promote cell proliferation and transformation, followed by a discussion of how loss-of-function mutations in differentiation pathways contribute to tumorigenesis. We will end this section with a description of how the molecular analysis of tumors is changing the manner in which cancer is treated. Personalized medicine—the ability to diagnose individual tumors at the molecular level and to design treatments for a patient’s specific cancer—is likely to become a reality in the twenty-first century.

Mouse Models of Human Cancer Teach Us About Disease Initiation and Progression

Genetically engineered mice have provided tremendous insights into the steps of tumor initiation and progression. For example, as shown previously in Figure 24-7, murine experiments revealed that mice overexpressing *Myc* develop tumors in the tissues where *Myc* is present at high levels, and tumor development is accelerated when *Myc* overproduction is combined with expression of an additional oncogene, lending support to the multi-hit model of cancer induction. The analysis of mice lacking key tumor-suppressor genes such as *RB* and *p53* also helped shape our understanding of how these genes function. However, using mouse models to study cancer is not always straightforward. Many tumor-suppressor genes serve essential functions during normal mouse development, and mice lacking both copies of these genes are not viable. The essential function of these genes early during embryogenesis precludes the study of their role in tumor progression. To circumvent this problem, researchers have begun to employ conditional “knock-in” and “knock-out” strategies that allow for the targeted activation or inactivation of a gene in a certain tissue and/or at a certain stage of development.

In the conditional mouse model, an allele of a particular oncogene or tumor suppressor gene is wild-type until activated or inactivated with exogenous chemicals or viruses in a tissue or time-specific manner. At the heart of conditional systems are the Cre and FLP recombinases. These recombinases facilitate homologous recombination between loxP and FRT sites, respectively (Figure 24-15). When the recombinases are driven by a tissue-specific promoter, recombination occurs only in the tissue that produces the recombinase. The recombinase system can be used in two ways. The recombinase target sites could flank an exon. On induction of the recombinase, the exon is lost and the gene is inactivated (Figure 24-15a). This system is especially useful to inactivate tumor suppressor genes in a tissue-specific manner. Expression of oncogenes can be controlled by introducing into the oncogene an additional exon that contains a stop codon. The oncogene with the stop-codon-containing exon is therefore not functional. However, if the additional exon is flanked by recombinase target sites, the oncogene will be produced on

FIGURE 24-15 Conditional mouse models of cancer. In the inactivating system (a), an exon is flanked by two loxP or FRT sites as shown. Expression of the Cre or FLP recombinase leads to homologous recombination between the two loxP and FRT sites, respectively. This leads to excision of the exon, rendering the gene nonfunctional. In the activating system (b), an additional exon with a STOP codon is introduced into the gene of interest, making the gene nonfunctional. This exon is flanked by loxP or FRT sites. When Cre or FLP recombinase is induced, the stop-codon-containing exon is recombined out and the gene of interest, such as an oncogenic form of *ras* with valine substituted for the glycine at position 12, is expressed.

induction of the recombinase (Figure 24-15b). Using this system, researchers have examined the role of oncogenic forms of Ras in the mouse and have, using this conditional oncogenic Ras allele, created a mouse model of human lung cancer.

The development of promoters that can be regulated by exogenously added chemicals has provided an additional powerful method to control gene expression within animals. Most widely used are the Tet-On and Tet-Off systems. Each system is composed of two parts: the Tet operon promoter that regulates the expression of the gene of interest and either the transactivator tTA (in the case of Tet-Off) or the reverse transactivator rtTA (in the case of Tet-On). Both transcription factors bind to the Tet operator to induce gene expression, and both are regulatable by tetracycline (or the tetracycline analog doxycycline, more commonly used by scientists in their experiments). The difference between the two systems lies in the responses of tTA and rtTA to doxycycline binding. Doxycycline inhibits tTA from binding the promoter. Thus in the Tet-Off system, addition of doxycycline turns off transcription. In the Tet-On system, rtTA cannot bind the promoter in the absence of drug and addition of doxycycline induces transcription. Doxycycline can be administered by simply adding it to the animals' water supply. Placing the Tet transcriptional regulators under the control of tissue-specific promoters therefore allows for temporal as well as spatial control of gene expression.

Using the Tet-Off system to control Myc expression, researchers found that survival of a tumor depends on the continuous production of Myc protein. When expression of Myc was even briefly interrupted, osteogenic sarcoma cells ceased dividing and developed into mature osteocytes (Figure 24-16). It is now clear that the continuous activity of oncogenes is required for the survival of many different tumors. This dependence of a tumor on the continuous production of an oncogene has been termed **oncogene addiction** and may provide new opportunities for treatment. Specific inhibitors of oncogenes—even when applied only transiently—could lead to disease regression.

Oncogenic Receptors Can Promote Proliferation in the Absence of External Growth Factors

Hyperactivation of a growth-inducing signaling protein due to an alteration of the protein might seem a likely mechanism of cancer, but in fact this rarely occurs. Only one such

naturally occurring oncogene, *sis*, has been discovered. The *sis* oncogene, which encodes an altered form of platelet-derived growth factor (PDGF), can aberrantly stimulate proliferation of cells that normally express the PDGF receptor. A more common event is that cancer cells begin to produce an unaltered growth factor that acts on the cell that produces it. This is called **autocrine stimulation**.

In contrast, oncogenes encoding cell-surface receptors that transduce growth-promoting signals have been associated with several types of cancer. Many of these receptors have intrinsic protein-tyrosine kinase activity in their cytosolic

EXPERIMENTAL FIGURE 24-16 Myc is continuously needed for tumor growth. Transgenic mice were developed in which *myc* expression was driven by the Tet-Off system. One percent of such mice develop osteogenic sarcomas. Wild-type mice were transplanted with osteogenic sarcomas and the *myc* gene was then inactivated by treating mice with doxycycline. This caused cessation of proliferation of osteogenic sarcomas (a) and differentiation into mature osteocytes (b). After *myc* withdrawal, cells also lost alkaline phosphatase activity, a marker for osteogenic sarcomas (c, d). Surprisingly, re-expression of Myc protein did not trigger a return to the sarcoma state. [From Meenakshi et al., 2002, *Science* 297:102.]

domains, an activity that is quiescent until activated. Ligand binding to the external domains of these **receptor tyrosine kinases (RTKs)** leads to their dimerization and activation of their kinase activity, initiating an intracellular signaling pathway that ultimately promotes proliferation.

In some cases, a point mutation changes a normal RTK into one that dimerizes and is constitutively active even in the absence of ligand. For instance, a single point mutation converts the normal human EGF receptor 2 (Her2) into the Neu oncoprotein ("neu" for its first known role, in neuroblastoma), which is an initiator of certain mouse cancers (Figure 24-17, *left*). Similarly, human tumors called *multiple endocrine neoplasia type 2* produce a constitutively active dimeric gliaderived neurotrophic factor (GDNF) receptor that results from a point mutation in the extracellular domain. GDNF receptor and Her2 receptor are protein-tyrosine kinases, so the constitutively active forms excessively phosphorylate

their downstream target proteins. In other cases, deletion of much of the extracellular ligand-binding domain produces a constitutively active oncogenic receptor. For example, deletion of the extracellular domain of the normal EGF receptor (Figure 24-17, *right*) converts it to the dimeric ErbB oncoprotein (from erythroblastosis virus, where a viral version of the altered gene was first identified).

Mutations leading to overproduction of a normal RTK also can be oncogenic. For instance, many human breast cancers overproduce a normal Her2 receptor. As a result, the cells are stimulated to proliferate in the presence of very low concentrations of EGF and related hormones, concentrations too low to stimulate proliferation of normal cells (see Chapter 16).

Viral Activators of Growth-Factor Receptors Act as Oncoproteins

Viruses use their own tricks to cause cancer, presumably to increase the production of virus from infected cancer cells. For example, a retrovirus called *spleen focus-forming virus (SFFV)* induces erythroleukemia (a tumor of erythroid progenitors) in adult mice by manipulating a normal developmental signal. The proliferation, survival, and differentiation of erythroid progenitors into mature red cells absolutely require erythropoietin (Epo) and the corresponding Epo receptor (see Figure 16-8). A mutant SFFV envelope glycoprotein, termed *gp55*, is responsible for the oncogenic effect of the virus. Although gp55 cannot function as a normal retrovirus envelope protein in virus budding and infection, it has acquired the remarkable ability to bind to and activate Epo receptors in the infected cell (Figure 24-18). By inappropriately and continuously stimulating the proliferation of erythroid

FIGURE 24-17 Effects of oncogenic mutations in proto-oncogenes that encode cell-surface receptors. *Left:* A mutation that alters a single amino acid (valine to glutamine) in the transmembrane region of the Her2 receptor causes dimerization of the receptor, even in the absence of the normal EGF-related ligand, making the oncoprotein Neu a constitutively active kinase. *Right:* A deletion that causes loss of the extracellular ligand-binding domain in the EGF receptor leads, for unknown reasons, to constitutive activation of the kinase activity of the resulting oncoprotein ErbB.

FIGURE 24-18 Activation of the erythropoietin (Epo) receptor by the natural ligand, Epo, or a viral oncoprotein. Binding of Epo dimerizes the receptor and induces formation of erythrocytes from erythroid progenitor cells. Normally cancers occur when progenitor cells infected by the spleen focus-forming virus produce the Epo receptor and viral gp55, both localized to the plasma membrane. The transmembrane domains of dimeric gp55 specifically bind the Epo receptor, dimerizing and activating the receptor in the absence of Epo. [See S. N. Constantinescu et al., 1999, *EMBO J.* 18:3334.]

progenitors, gp55 induces formation of excessive numbers of erythrocytes. Malignant clones of erythroid progenitors emerge several weeks after SFFV infection as a result of further mutations in these aberrantly proliferating cells.

Another example of this phenomenon is provided by human papillomavirus (HPV), the sexually transmitted DNA virus that causes cervical cancer and genital warts. A papillomavirus protein designated E5, which contains only 44 amino acids, spans the plasma membrane and forms a dimer or trimer. Each E5 polypeptide can form a stable complex with one endogenous receptor for PDGF, thereby aggregating two or more PDGF receptors within the plane of the plasma membrane. This mimics hormone-mediated receptor dimerization, causing sustained receptor activation and eventually cell transformation. As we will see later, the HPV genome also codes for several other proteins that act to inhibit tumor-suppressor genes, further contributing to cell transformation. Recently a vaccine against an HPV capsid protein (L1) has been found to protect against cervical cancer caused by at least some subtypes of HPV.

Many Oncogenes Encode Constitutively Active Signal Transduction Proteins

A large number of oncogenes are derived from proto-oncogenes whose encoded proteins aid in transducing signals from an activated receptor to a cellular target. We describe several examples of such oncogenes; each is expressed in many types of tumor cells.

Ras Pathway Components Among the best-studied oncogenes in this category are the *ras^D* genes, which were the first nonviral oncogenes to be recognized. Any one of a number of changes in Ras protein can lead to its uncontrolled and therefore dominant activity. In particular, if a point mutation substitutes any amino acid for the glycine at position 12 in the Ras sequence, the normal protein is converted into a constitutively active oncoprotein. This simple mutation reduces the protein's GTPase activity, thus maintaining Ras in the active GTP-bound state. Constitutively active Ras oncoproteins are produced by many types of human tumors, including bladder, colon, mammary, skin, and lung carcinomas, neuroblastomas, and leukemias.

As we saw in Chapter 16, Ras is a key component in transducing signals from activated receptors to a cascade of protein kinases. In the first part of this pathway, a signal from an activated RTK is carried via two adapter proteins to Ras, converting it to the active GTP-bound form (see Figure 16-20). In the second part of the pathway, activated Ras transmits the signal via two intermediate protein kinases to MAP kinase. The activated MAP kinase then phosphorylates a number of transcription factors that induce synthesis of important cell-cycle and differentiation-specific proteins (see Figure 16-24). Activating Ras mutations short-circuit the first part of this pathway, making upstream activation triggered by ligand binding to the receptor unnecessary. Oncogenes encoding other altered components of the RTK/Ras/MAP kinase pathway also have been identified.

Constitutive Ras activation can also arise from a recessive loss-of-function mutation in a GTPase-activating protein (GAP). The normal GAP function is to accelerate hydrolysis of GTP and the conversion of active GTP-bound Ras to inactive GDP-bound Ras (see Figure 3-32). The loss of GAP leads to sustained Ras activation of downstream signal transduction proteins. For example, neurofibromatosis, a benign tumor of the sheath cells that surround nerves, is caused by loss of both alleles of *NF1*, which encodes a Ras GAP-type protein. Individuals with neurofibromatosis have inherited a single mutant *NF1* allele; subsequent somatic mutation in the other allele leads to formation of neurofibromas. Thus *NF1*, like *RB*, is a tumor-suppressor gene, and the tendency

FIGURE 24-19 Structure of Src tyrosine kinases and activation by an oncogenic mutation. (a) Three-dimensional structure of Hck, one of several Src kinases in mammals. Phosphorylation of tyrosine 527 in the SH2 domain induces conformational strains in the SH3 and kinase domains, distorting the kinase active site so it is catalytically inactive. The kinase activity of cellular Src proteins is normally activated by removing the phosphate on tyrosine 527. (b) Domain structure of c-Src and v-Src. Phosphorylation of tyrosine 527 by Csk, another cellular tyrosine kinase, inactivates the Src kinase activity. The transforming v-Src oncoprotein encoded by Rous sarcoma virus is missing the C-terminal 18 amino acids, including tyrosine 527, and thus is constitutively active. [Part (a) from F. Sicheri et al., 1997, *Nature* **385**:602; see also T. Pawson, 1997, *Nature* **385**:582, and W. Xu et al., 1997, *Nature* **385**:595.]

FIGURE 24-20 Bcr-Abl protein kinase. (a) Origin of the Philadelphia chromosome from a translocation of the tips of chromosomes 9 and 22 and the oncogenic fusion protein formed by the Philadelphia chromosome translocation. (b) The Bcr-Abl fusion protein is a constitutively active kinase that phosphorylates multiple signal transduction proteins. Imatinib binds to the active site of Bcr-Abl and inhibits its kinase activity. (c) Imatinib bound to the Bcr-Abl active site. [Part (c) from Nagar et al., 2002, *Cancer Research* 62:4236.]

SH3 protein-protein interaction domains. The kinase activity of cellular Src and related proteins normally is inactivated by phosphorylation of the tyrosine residue at position 527, which is six residues from the C-terminus (Figure 24-19a). Hydrolysis of phosphotyrosine 527 by a specific phosphatase enzyme normally activates c-Src. Tyrosine 527 is often missing or altered in Src oncoproteins that have constitutive kinase activity; that is, they do not require activation by a phosphatase (Figure 24-19b).

Abl Protein Kinase One oncogene encoding a cytosolic non-receptor protein kinase is generated by a chromosome translocation that fuses a part of the *c-abl* gene, which encodes a tyrosine kinase, with part of the *bcr* gene, whose function is unknown (Figure 24-20a). One consequence of the fusion is that a hybrid protein is produced, and it has odd and dangerous properties. The normal c-Abl protein promotes branching of filamentous actin and extension of cell processes, so it may function primarily to control the cytoskeleton and cell shape. The chimeric oncoproteins encoded by the *bcr-abl* oncogene form a tetramer that exhibits unregulated and continuous Abl kinase activity (Figure 24-20b). Bcr-Abl can phosphorylate and thereby activate many intracellular signal transduction proteins, and at least some of these proteins are not normal substrates of Abl. For instance, Bcr-Abl can activate JAK2 kinase and STAT5 transcription factor, which normally are activated by binding of growth factors (e.g., erythropoietin) to cell-surface receptors (see Figure 16-10). Bcr-Abl can also provide a docking site for signal transduction proteins through the Bcr part, thus potentially stimulating signal transduction.

The chromosomal translocation that forms *bcr-abl* generates the diagnostic *Philadelphia chromosome*, discovered in 1960 (see Figure 24-20a). If this translocation occurs in a hematopoietic cell in the bone marrow, the activity of the chimeric *bcr-abl* oncogene results in the initial phase of human

to develop neurofibromatosis, like hereditary retinoblastoma, is inherited as an autosomal dominant trait.

Src Protein Kinase Several oncogenes encode cytosolic protein kinases that normally transduce signals in a variety of intracellular signaling pathways. Indeed, the first oncogene to be discovered, *v-src* from Rous sarcoma retrovirus, encodes a constitutively active protein-tyrosine kinase. At least eight mammalian proto-oncogenes encode a family of non-receptor tyrosine kinases related to the v-Src protein. In addition to a catalytic domain, these kinases contain SH2 and

chronic myelogenous leukemia (CML), characterized by an expansion in the number of white blood cells. A second loss-of-function mutation in a cell carrying *bcr-abl* (e.g., in *p53* or *RB*) leads to acute leukemia, which is often fatal. The CML chromosome translocation was only the first of a long series of distinctive, or “signature,” chromosome translocations linked to particular forms of leukemia. Many of the gene fusions involve genes encoding transcriptional regulators, particularly transcriptional regulators of Hox genes, a group of transcription factors required for cell proliferation and differentiation during embryonic development. Each case presents an opportunity for greater understanding of the disease, earlier diagnosis, and new therapies. In the case of CML, that second step to successful therapy has already been taken.

After a painstaking search, an inhibitor of Abl kinase named imatinib (Gleevec) was identified as a possible treatment for CML in the early 1990s. Imatinib, which binds directly to the Abl kinase active site and inhibits kinase activity, is highly lethal to CML cells while sparing normal cells (Figure 24-20c). After clinical trials showing imatinib is remarkably effective in treating CML despite some side effects, it was approved by the FDA in 2001, the first cancer drug targeted to a signal transduction protein unique to tumor cells. Imatinib inhibits several other tyrosine kinases that are implicated in different cancers and has been successful in trials for treating these diseases, including forms of gastrointestinal tumors, as well. There are 90 functional tyrosine kinases encoded in the human genome, so drugs related to imatinib may be useful in controlling the activities of all these proteins. One ongoing challenge is that tumor cells can evolve to be resistant to imatinib and other such drugs, necessitating the invention of alternative drugs. ■

Inappropriate Production of Nuclear Transcription Factors Can Induce Transformation

Oncogenic mutations that create oncogenes or damage tumor-suppressor genes eventually cause changes in gene expression. Experimentally this can be measured by comparing the amounts of different mRNAs produced in normal versus tumor cells. As discussed earlier, we can now measure such differences in the expression of thousands of genes with DNA microarrays (see Figure 24-10).

Since the most direct effect on gene expression is exerted by transcription factors, it is not surprising that many oncogenes encode transcription factors. Two examples are *jun* and *fos*, which initially were identified in transforming retroviruses and later found to be overexpressed in some human tumors. The *c-jun* and *c-fos* proto-oncogenes encode proteins that sometimes associate to form a heterodimeric transcription factor, called *AP1*, that binds to a sequence found in promoters and enhancers of many genes (see Figure 7-32a and Chapter 16). Both Fos and Jun also can act independently as transcription factors. They function as oncoproteins by activating transcrip-

tion of key genes that encode growth-promoting proteins or by inhibiting transcription of growth-repressing genes.

Many nuclear proto-oncogene proteins are produced when normal cells are stimulated to grow, indicating their direct role in growth control. For example, PDGF treatment of quiescent 3T3 cells induces an approximately 50-fold increase in the production of c-Fos and c-Myc, the normal products of the *fos* and *myc* proto-oncogenes. Initially there is a transient rise of c-Fos and later a more prolonged rise of c-Myc (Figure 24-21). The levels of both proteins decline within a few hours, a regulatory effect that may, in normal cells, help to avoid cancer. c-Fos and c-Myc stimulate transcription of genes encoding proteins that promote progression through the G_1 phase of the cell cycle and the G_1 -to-S transition. In tumors, the oncogenic forms of these or other transcription factors are frequently expressed at high and unregulated levels.

In normal cells, c-Fos and c-Myc mRNAs and the proteins they encode are intrinsically unstable, leading to their rapid degradation after the genes are induced. Some of the changes that turn *c-fos* from a normal gene into an oncogene involve genetic deletions of the sequences that make the Fos mRNA and protein short lived. Conversion of the *c-myc* proto-oncogene into an oncogene can occur by different mechanisms. In cells of the human tumor known as *Burkitt's lymphoma*, the *c-myc* gene is translocated to a site near the heavy-chain antibody genes, which are normally active in antibody-producing white blood cells (Figure 24-22). The *c-myc* translocation is a rare aberration of the normal DNA rearrangements that occur during maturation of antibody-producing cells. The translocated *myc* gene, now regulated by the antibody gene enhancer, is continually expressed, causing the cell to become cancerous. Localized amplification of a segment of DNA containing the *myc* gene, which

EXPERIMENTAL FIGURE 24-21 Addition of serum to quiescent 3T3 cells yields a marked increase in the activity of two proto-oncogene products, c-Fos and c-Myc. Serum contains factors such as platelet-derived growth factor (PDGF) that stimulate the growth of quiescent cells. One of the earliest effects of growth factors is to induce expression of *c-fos* and *c-myc*, whose encoded proteins are transcription factors. [See M. E. Greenberg and E. B. Ziff, 1984, *Nature* 311:433.]

FIGURE 24-22 Chromosomal translocation in Burkitt's lymphoma.

As a result of a translocation between chromosomes 8 and 14, the *c-myc* gene is placed adjacent to the gene for part of the antibody heavy chain (C_H), leading to overproduction of the Myc transcription factor in lymphocytes and hence their growth into a lymphoma.

occurs in several human tumors, also causes inappropriately high production of the otherwise normal Myc protein.

The *c-myc* gene encodes a basic helix-loop-helix zipper protein that acts as part of a set of interacting proteins that can dimerize in various combinations, bind to DNA, and coordinately regulate the transcription of target genes. Other members of the protein set include Mad, Max, and Mnt. Max can heterodimerize with Myc, Mad, and Mnt. Myc-Max dimers regulate genes that control proliferation, such as cyclins. Mad proteins inhibit Myc proteins, which has led to an interest in using Mad proteins, or drugs that stimulate Mad proteins, to rein in excessive Myc activity that contributes to tumor formation. Myc protein complexes affect transcription by recruiting chromatin-modifying complexes containing histone acetyltransferases (which usually stimulate transcription; see Chapter 7) to Myc target genes. Mad and Mnt work with the Sin3 co-repressor protein to bring in histone deacetylases that help to block transcription. Together, all these proteins form a regulatory network that employs protein-protein association, variations in DNA binding, and transcriptional regulation to control cell proliferation. Overproduction of Myc protein tips the scales in favor of cell division and growth.

Aberrations in Signaling Pathways That Control Development Are Associated with Many Cancers

During normal development, secreted signals such as Hedgehog (Hh), Wnt, and TGF- β are frequently used to direct cells to particular developmental fates, which may include the property of rapid mitosis. The effects of such signals must be regulated so that growth is limited to the right time and place. Among the mechanisms available for reining in the effects of powerful developmental signals are inducible intracellular antagonists, receptor blockers, and competing signals. Mutations that prevent such restraining mechanisms from operating are likely to be oncogenic, causing inappropriate or cancerous growth.

Hh signaling, which is used repeatedly during development to control cell fates, is a good example of a signaling pathway

implicated in cancer induction. In the skin and cerebellum, one of the human Hh proteins, Sonic hedgehog, stimulates cell division by binding to and inactivating a membrane protein called Patched1 (Ptc1) (see Figure 16-33). Loss-of-function mutations in *ptc1* permit cell proliferation in the absence of an Hh signal; thus *ptc1* is a tumor-suppressor gene. People who inherit a single working copy of *ptc1* have a propensity to develop skin and brain cancer; either can occur when the remaining allele is damaged. Other people can get these diseases too if they suffer loss of both copies of the gene. Thus there are both familial (inherited) and sporadic (noninherited) cases of these diseases, just as in retinoblastoma. Mutations in other genes in the Hh signaling pathway are also associated with cancer. Some such mutations create oncogenes that turn on Hh target genes inappropriately; others are recessive mutations that affect negative regulators such as Ptc1. As is the case for a number of other tumor-suppressor genes, complete loss of Ptc1 function would lead to early fetal death since it is needed for development, so it is only the tumor cells that are homozygous *ptc1/ptc1*.

Many of the signaling pathways described in other chapters play roles in controlling embryonic development and cell proliferation in adult tissues. In recent years mutations affecting components of most of these signaling pathways have been linked to cancer. Indeed, once one gene in a developmental pathway has been linked to a type of human cancer, knowledge of the pathway gleaned from model organisms such as worms, flies, or mice allows focused investigations of the possible involvement of additional pathway genes in other cases of the cancer. For example, *APC*, a critical gene mutated on the path to colon carcinoma, is now known to be part of the Wnt signaling pathway (see Chapter 16), which led to the discovery of the involvement of β -catenin mutations in colon cancer. Mutations in tumor-suppressor developmental genes promote tumor formation in tissues where the affected gene normally helps restrain growth. Thus the tumor-suppressor gene mutations will not cause cancers in tissues where the primary role of the developmental regulator is to control cell fate—what type of cell develops—but not cell division. Mutations in developmental proto-oncogenes may induce tumor formation in tissues where an affected gene normally promotes cell proliferation or in another tissue where the gene has become aberrantly active.

Transforming growth factor β (TGF- β), despite its name, inhibits proliferation of many cell types, including most epithelial and immune-system cells. Binding of TGF- β to its receptor induces activation of cytosolic Smad transcription factors (see Figure 16-28). After translocating to the nucleus, Smads can promote expression of the gene encoding p15, an inhibitor of cyclin-dependent kinase 4 (CDK4), which causes cells to arrest in G_1 . TGF- β signaling also promotes expression of genes encoding extracellular matrix proteins and plasminogen activator inhibitor 1 (PAI-1), which reduces the plasmin-catalyzed degradation of the matrix. Loss-of-function mutations in either TGF- β receptors or in Smads thus promote cell proliferation and probably contribute to the invasiveness and metastasis of tumor cells (Figure 24-23). Such

FIGURE 24-23 Effect of loss of TGF- β signaling. Binding of TGF- β , an anti-growth factor, causes activation of Smad transcription factors. In the absence of effective TGF- β signaling owing to either a receptor mutation or a SMAD mutation, cell proliferation and invasion of the surrounding extracellular matrix (ECM) increase. [See X. Hua et al., 1998, *Genes & Dev.* 12:3084.]

mutations have in fact been found in a variety of human cancers. For example, deletion of the *Smad4* gene occurs in many human pancreatic cancers; retinoblastoma and colon cancer cells lack functional TGF- β receptors and therefore are unresponsive to TGF- β growth inhibition.

Molecular Cell Biology Is Changing How Cancer Is Treated

The imatinib story described earlier illustrates how genetics—the discovery of the Philadelphia chromosome and the critical oncogene it creates—together with biochemistry—the discovery of the molecular action of the Abl protein—can lead to a powerful new therapy. In general, each difference between cancer cells and normal cells provides a new opportunity to identify a specific drug or treatment that kills just the cancer cells or at least stops their uncontrolled growth. Thus knowledge of the molecular cell biology of the tumors is critical information that can be exploited by researchers to develop anticancer treatments that more precisely target just cancer cells.

 Breast cancer provides a good example of how molecular cell biology techniques have affected treatments, both curative and palliative. Until the rise in the incidence of lung cancer, resulting from an increase in women smokers, breast cancer was the most deadly cancer for women, and it remains the second most frequent cause of women's cancer deaths. The cause of breast cancer is unknown, but the frequency is increased if certain mutations are carried. Breast cancers are often diagnosed during routine mammogram (x-ray) examinations. Typically, a biopsy of a 1–2-cm tissue mass is taken to check the diagnosis and is tested with antibodies to determine whether a high level of estrogen or progesterone receptor is present. These steroid receptors are capable of stimulating tumor growth and are sometimes expressed at high levels in breast cancer cells. If either receptor is present, it is exploited in the treatment. A drug called tamoxifen, which inhibits the estrogen receptor, can be used to deprive the tumor cells of a growth-stimulating hormone. The biopsy is also tested for amplification of the proto-oncogene *HER2/NEU*, which, as we have seen, encodes human EGF receptor 2. A monoclonal antibody specific for Her2 has been a strikingly successful new treatment for the subset of breast cancers that overproduce Her2. Her2 antibody injected

into the blood recognizes Her2 and causes it to be internalized, selectively killing the cancer cells without any apparent effect on normal breast (and other) cells that produce moderate amounts of Her2. Similarly, many lung cancers harbor an amplification of the EGF receptor locus. Treatment with the EGFR inhibitor erlotinib has dramatically increased life expectancy of patients with this type of lung cancer.

Breast cancer is treated with a combination of surgery, radiation therapy, and chemotherapy. The first step is surgical resection (removal) of the tumor and examination of lymph nodes for evidence of metastatic tumor, which is the major adverse prognostic factor. The subsequent treatment involves 6 weeks of radiation and 8 weeks of chemotherapy

with three different types of agents. These harsh treatments are designed to kill the dividing cancer cells; however, they also cause a variety of side effects, including suppression of blood cell production, hair loss, nausea, and neuropathy. This can reduce the strength of the immune system, risking infection, and cause weakness due to poor oxygen supply. To help, patients are given the growth factor G-CSF to promote neutrophil formation (a type of white blood cell that fights bacterial and fungal infections) and erythropoietin (Epo) to stimulate red blood cell formation. Despite all this treatment, an average-risk woman (60 years old, 2-cm tumor, 1 positive lymph node) has a 30–40 percent 10-year risk of succumbing to her cancer. This risk can be reduced by 10–15 percent by hormone-blocking treatment such as tamoxifen, exploiting the molecular data that show a hormone receptor present on the cancer cells. Mortality is reduced another 5–10 percent by treatment with antibodies against the Her2/Neu oncoprotein. Thus molecular biology is having a huge impact on breast cancer victim survival rates, though still far less than one would like. ■

To identify more genetic alterations unique to a tumor that could be exploited for new therapies, researchers now utilize RNAi technologies to identify genes that when inactivated cause tumor cells but not normal cells to die. This approach of identifying *synthetic lethal* interactions between genetic alterations, which on their own are not lethal, was first pioneered in budding yeast. With the development of genome-wide short hairpin (sh)RNAi libraries (a collection of RNAi constructs that target every gene in the human genome; see Chapter 5), this approach is now also feasible in human cells. Tumor cells and normal cells are infected with pools of shRNAi constructs, each of which harbors a unique sequence tag known as a bar code. After a period of growth the RNAi constructs can be isolated and shRNAs that were lost from the pool can be identified by deep sequencing of the remaining constructs. The shRNAs that were lost point to the target gene being essential for viability in this cell type. shRNA constructs that cause lethality in tumor cells but not normal cells suggests that a gene is essential for the survival of a tumor cell but not a normal cell. For example, this approach has been used to identify genes that when inactivated cause selective lethality in cancer cells harboring an oncogenic form of *ras*, the *K-ras* oncogene. Genes encoding proteins essential for mitotic progression such as the ubiquitin ligase APC/C (see Chapter 19) were found to be synthetic lethal with the *K-ras* allele. These proteins could provide novel targets for the development of new therapeutics for tumors that harbor oncogenic forms of *ras*.

The vision for the future of medicine is that the need for radiation, chemotherapy, and perhaps even surgery will be substantially reduced, thus reducing toxicity and collateral damage. Increased knowledge of the molecular cell biology of cancer will allow drugs to be administered that are, first, more effective and harmless and, second, tuned to the particular properties of an individual's tumor cells. In breast and lung cancer tumor treatment we can already see progress in this direction.

KEY CONCEPTS of Section 24.3

Cancer and the Misregulation of Growth Regulatory Pathways

- Mice in which oncogenes and tumor-suppressor genes can be expressed in a tissue-specific or temporal way teach us about how cancers arise and how they contribute to disease progression.
- Mutations or chromosomal translocations that permit RTKs for growth factors to dimerize in the absence of their normal ligands lead to constitutive receptor activity (see Figure 24-17). Such activation ultimately induces changes in gene expression that can transform cells. Overproduction of growth-factor receptors can have the same effect and lead to abnormal cell proliferation.
- Certain virus-encoded proteins can bind to and activate host-cell receptors for growth factors, thereby stimulating cell proliferation in the absence of normal signals.
- Most tumor cells produce constitutively active forms of one or more intracellular signal transduction proteins, causing growth-promoting signaling in the absence of normal growth factors.
- A single point mutation in Ras, a key transducing protein in many signaling pathways that promote cell proliferation and differentiation, reduces its GTPase activity, thereby maintaining it in an activated state.
- The activity of Src, a cytosolic signal-transducing protein-tyrosine kinase, normally is regulated by reversible phosphorylation and dephosphorylation of a tyrosine residue near the C-terminus (see Figure 24-19). The unregulated activity of Src oncoproteins that lack this tyrosine promotes abnormal proliferation of many cells.
- The Philadelphia chromosome results from a chromosomal translocation that produces the chimeric *bcr-abl* oncogene. The unregulated Abl kinase activity of the Bcr-Abl oncoprotein is responsible for its oncogenic effect. An Abl kinase inhibitor (imatinib, or Gleevec) is effective in treating chronic myelogenous leukemia (CML) and may work against a few other cancers that are driven by related kinases (see Figure 24-20).
- Inappropriate production of nuclear transcription factors such as Fos, Jun, and Myc can induce transformation. In Burkitt's lymphoma cells, *c-myc* is translocated close to an antibody gene, leading to overproduction of c-Myc (see Figure 24-22).
- Many genes that regulate normal developmental processes encode proteins that function in various signaling pathways. Their normal roles in regulating where and when growth occurs are reflected in the character of the tumors that arise when the genes are mutated.
- Loss of signaling by TGF- β , a negative growth regulator, promotes cell proliferation and development of malignancy (see Figure 24-23).

- Precise molecular analysis of early tumors is allowing the use of highly targeted drug treatments that are likely to be optimal for a particular case of a particular tumor. These refinements have allowed substantial reduction in breast cancer mortality. There are good prospects for still better targeting of treatments based on continuing increases in the understanding of tumor-cell regulation.
- The advent of molecular techniques for characterizing individual tumors is allowing the application of drugs and antibody treatments that target the properties of a particular tumor. This permits more effective treatment of individual patients and reduces the use of drugs or antibodies that will be ineffective and possibly toxic.
- Novel shRNA screening methodologies allow for the identification of genes specifically required for the survival of cancer cells, thereby facilitating the discovery of new therapeutic targets.

24.4 Cancer and Mutation of Cell Division and Checkpoint Regulators

The complex mechanisms regulating the eukaryotic cell cycle are prime targets for oncogenic mutations. Both positive- and negative-acting proteins precisely control the entry of cells into and their progression through the cell cycle, which consists of four main phases: G_1 , S, G_2 , and mitosis (see Figure 19-30). In addition, cells harbor surveillance mechanisms—known as checkpoint pathways—that ensure that cells do not enter the next phase of the cell cycle before the previous one has been completed. For example, cells that have sustained damage to their DNA normally are arrested before their DNA is replicated or in G_2 before chromosome segregation. This arrest allows time for the DNA damage to be repaired; alternatively, the arrested cells are directed either to commit suicide via programmed cell death or at least not to divide. The whole cell-cycle control and checkpoint systems function to prevent cells from becoming cancerous. As might be expected, mutations in this system often lead to abnormal development or contribute to cancer.

In this section we will discuss the cell cycle and checkpoint pathways that are affected in cancer. We will first describe how the pathway that controls entry into the cell cycle is mutated and misregulated in most human cancers. We will then discuss how p53 prevents tumorigenesis by helping cells to respond to DNA damage. Next we will describe how mutations in programmed cell death pathways contribute to tumorigenesis and end with a discussion of an emerging group of important oncogenes and tumor-suppressor genes: micro-RNAs.

Mutations That Promote Unregulated Passage from G_1 to S Phase Are Oncogenic

Once a cell progresses past a certain point in late G_1 , called START, it becomes irreversibly committed to entering the S phase and replicating its DNA (see Figure 19-15). D-type

FIGURE 24-24 START control. Unphosphorylated Rb protein binds transcription factors collectively called E2F and thereby prevents E2F-mediated transcriptional activation of many genes whose products are required for DNA synthesis (e.g., DNA polymerase). The kinase activity of cyclin D–CDK4/6 phosphorylates Rb, thereby inactivating Rb and activating E2F; cyclin D–CDK4/6 activity is inhibited by p16. Overproduction of cyclin D, a positive regulator, or loss of the negative regulators p16 and Rb commonly occurs in human cancers.

cyclins, cyclin-dependent kinases (CDKs), and the Rb protein are all elements of the control system that regulates passage through START.

The pathway that controls entry into the cell cycle is estimated to be misregulated in approximately 80 percent of human cancers. At the heart of this pathway are cyclin D–CDK4/6 complexes and the transcription inhibitor Rb (Figure 24-24). The expression of D-type cyclin genes is induced by many extracellular growth factors, or **mitogens**. These cyclins assemble with their partners CDK4 or CDK6 to generate catalytically active cyclin–CDK complexes, whose kinase activity promotes progression through G_1 . Mitogen withdrawal prior to passage through START leads to accumulation of p15 or p16. As described in Chapter 19, p15 and p16 are CDK inhibitors that bind to cyclin D–CDK4/6 complexes and inhibit their activity, thereby causing G_1 arrest. The transcription inhibitor Rb is controlled by cyclin D–CDK4/6 phosphorylation. Unphosphorylated Rb binds to and sequesters E2F transcription factors in the cytoplasm. E2F transcription factors stimulate transcription of genes encoding proteins required for DNA synthesis. Under normal circumstances, phosphorylation of Rb protein is initiated midway through G_1 by active cyclin D–CDK4/6 complexes. Rb phosphorylation is completed by cyclin E–CDK2 complexes in late G_1 , allowing release and activation of E2F transcription factors and G–S progression. The complete phosphorylation of Rb and its disassociation from E2F irreversibly commits the cell to DNA synthesis.

Most tumors contain an oncogenic mutation that causes overproduction or loss of one of the components of the pathway that controls entry into S phase such that the cells are propelled into S phase in the absence of the proper extracellular growth signals. For example, elevated levels of cyclin D1,

one of the three D-type cyclins, are found in many human cancers. In certain tumors of antibody-producing B lymphocytes, the *cyclin D1* gene is translocated such that its transcription is under control of an antibody-gene enhancer, causing elevated cyclin D1 production throughout the cell cycle irrespective of extracellular signals. (This phenomenon is analogous to the *c-myc* translocation in Burkitt's lymphoma cells discussed earlier.) That cyclin D1 can function as an oncoprotein was shown by studies with transgenic mice in which the *cyclin D1* gene was placed under control of an enhancer specific for mammary ductal cells. Initially the ductal cells underwent hyperproliferation, and eventually breast tumors developed in these transgenic mice. Amplification of the *cyclin D1* gene and concomitant overproduction of the cyclin D1 protein is common in human breast cancer; the extra cyclin D1 helps to drive cells through the cell cycle.

We have already seen that inactivating mutations in both *RB* alleles lead to childhood retinoblastoma, a relatively rare type of cancer. However, loss of *RB* gene function also is found in more common cancers that arise later in life (e.g., carcinomas of lung, breast, and bladder). These tissues, unlike retinal tissue, most likely produce other proteins (e.g., p107 and p130, both structurally related to Rb) whose function is redundant with that of Rb, and thus loss of Rb is not so critical for developing cancer in these tissues. In the retina, however, regulation of cell cycle entry appears to rely exclusively on the Rb protein, which is why patients heterozygous for the *Rb* gene first develop tumors in this tissue. In addition to inactivating mutations, Rb function can be eliminated by the binding of an inhibitory protein, designated E7, that is encoded by human papillomavirus (HPV), another nasty viral trick to create virus-producing tissue. At present, this is known to occur only in cervical cancer.

The proteins that function as cyclin-CDK inhibitors play an important role in regulating the cell cycle. In particular, loss-of-function mutations that prevent p16 from inhibiting cyclin D-CDK4/6 kinase activity are common in several human cancers. As Figure 24-24 makes clear, loss of p16 mimics overproduction of cyclin D1. Thus p16 normally acts as a tumor suppressor. Although the *p16* tumor-suppressor gene is deleted in some human cancers, in others the *p16* sequence is normal. In some of these latter cancers (e.g., lung cancer) the *p16* gene, or genes encoding other functionally related proteins, is inactivated by hypermethylation of its promoter region, which prevents transcription. What promotes this change in the methylation of *p16* is not known, but it prevents production of this important cell-cycle-control protein.

The locus encoding p16 is highly unusual in that it encodes no less than three tumor-suppressor genes, making it the most highly vulnerable locus in the human genome. In addition to harboring the p16-encoding gene *INK4a*, immediately upstream is the *INK4b* locus, which encodes p15, another cyclin D-CDK4/6 inhibitor (Figure 24-25). The locus codes for a key activator of the tumor suppressor p53 as well as these CDK inhibitors. p14ARF (p19ARF in the mouse) is encoded by an exon upstream of the first *INK4a* exon and shares exon 2 and exon 3 with *INK4a*. As we will see in the next section, this

FIGURE 24-25 The *INK4b-ARF-INK4a* locus. This locus encodes three tumor-suppressor genes. Exons are designated as E. The two *INK4b* exons (orange) are located upstream of the *ARF/INK4a* locus. *ARF* (blue) is encoded by a unique E1β exon but shares exons E2 and E3 with *INK4a* (green). *INK4b* and *INK4a* encode p15 and p16 respectively. *ARF* encodes a p53 activator. [Adapted from Sherr, 2006. *Nat. Rev. Cancer* 6:663–673.]

protein controls the stability of p53. Thus mutations in this locus would simultaneously affect the two major tumor-suppressor pathways in the cell, the Rb and p53 pathways.

Loss of p53 Abolishes the DNA Damage Checkpoint

p53 is a central player in tumorigenesis. It is thought that most if not all human tumors either have mutations in p53 itself or proteins that regulate p53 activity. Cells with functional p53 become arrested in G₁ when exposed to DNA-damaging irradiation, whereas cells lacking functional p53 do not. Unlike other cell cycle proteins, p53 is present at very low levels in normal cells because it is extremely unstable and rapidly degraded. Mice lacking p53 are largely viable and healthy except for a predisposition to develop multiple types of tumors.

In normal mice the amount of p53 protein is heightened, a post-transcriptional response, only in stressful situations such as ultraviolet or γ irradiation, heat, and low oxygen. Irradiation by γ rays creates lesions in the DNA. Serine kinases ATM and/or ATR are recruited to these sites of damage and are activated. They then phosphorylate p53 on a serine residue in the N-terminus of the protein. This causes the protein to evade ubiquitin-mediated degradation, leading to a marked increase in its concentration (Figure 24-26). The stabilized p53 activates transcription of the gene encoding p21^{CIP}, which binds to and inhibits mammalian cyclin E-CDK2 and a plethora of other genes. As a result, cells with damaged DNA are arrested in G₁, allowing time for DNA repair by mechanisms discussed in Chapter 4, or the cells permanently arrest, that is, become senescent. The activity of p53 is not limited to inducing cell cycle arrest. In addition, this multipurpose tumor suppressor stimulates production of pro-apoptotic proteins (see the next section) and DNA-repair enzymes (see Figure 24-26). Senescence and apoptosis may in fact be the most important means through which p53 prevents tumor growth.

The activity of p53 normally is kept low by a protein called Mdm2. When Mdm2 is bound to p53, it inhibits the transcription-activating ability of p53 and at the same time, because it has E3 ubiquitin ligase activity, catalyzes the ubiquitinylation of p53, thus targeting p53 for proteasomal degradation. Phosphorylation of p53 by ATM or ATR displaces

FIGURE 24-26 G₁ arrest in response to DNA damage. The kinase activity of ATM is activated in response to DNA damage due to various stresses (e.g., UV irradiation, heat). Activated ATM then triggers three pathways leading to arrest in G₁: (1) Chk2 is phosphorylated and, in turn, phosphorylates Cdc25A, thereby marking it for degradation and blocking its role in CDK2 activation. (2) In a second pathway, phosphorylation of p53 stabilizes it, permitting p53-activated expression of genes encoding proteins that cause arrest in G₁, promote apoptosis, or participate in DNA repair. (3) The third pathway is another way of controlling the pool of p53. The Mdm2 protein in its active form can form a complex with p53, inhibiting the transcription

factor and causing p53 ubiquitination and subsequent degradation by the proteasome. ATM phosphorylates Mdm2 to inactivate it, causing increased stabilization of p53. In addition, Mdm2 levels are controlled by p14ARF (p19ARF in mice), which binds Mdm2 and sequesters it in the nucleolus, where it cannot access p53. The p14ARF gene is induced by high levels of mitogenic signaling that is frequently observed in cells carrying oncogenic mutations in growth factor signaling pathways. The human *Mdm2* gene is frequently amplified in sarcomas, which presumably causes excessive inactivation of p53. Similarly, p14ARF is also found mutated in some cancers.

bound Mdm2 from p53, thereby stabilizing it. Because the *Mdm2* gene is itself transcriptionally activated by p53, Mdm2 functions in an autoregulatory feedback loop with p53, perhaps normally preventing excess p53 function. The *Mdm2* gene is amplified in many sarcomas and other human tumors that contain a normal p53 gene. Even though functional p53 is produced by such tumor cells, the elevated Mdm2 levels reduce the p53 concentration enough to abolish the p53-induced G₁ arrest in response to irradiation. A key regulator of the Mdm2 ubiquitin ligase is the p14ARF (p19 in mouse) protein, encoded by the multi-tumor-suppressor locus that also encodes the INK4 proteins. p14ARF binds to and sequesters Mdm2 in the nucleolus—in this manner causing stabilization of p53. Normal p14ARF levels are so low in tissues that the protein is barely detectable. This is good because it would otherwise cause p53 accumulation and hence cell cycle arrest or apoptosis. However, in response to oncogenic signaling, that is, in the presence of high levels of mitogenic signals, p14ARF transcription is induced by the E2F transcription factor (see Figure 24-26). Thus ARF is an important inhibitor of tumorigenesis since it induces p53 activation, when mitogenic

signaling reaches unphysiologically high levels, through hyperactivating mutations in the signaling pathways. For that reason, for mitogenic signaling pathways to cause uncontrolled proliferation as is seen in cancer, this p53 up-regulation must not occur. It is therefore not surprising that p53 is inactive in most human tumors, either through loss of p53 function itself or through down-regulation of positive regulators of p53 function such as p14ARF or up-regulation of negative regulators of p53 such as Mdm2.

The activity of p53 also is inhibited by a human papillomavirus (HPV) protein called E6. HPV encodes three proteins that contribute to its ability to induce stable transformation and mitosis in a variety of cultured cells. Two of these—E6 and E7—bind to and inhibit the p53 and Rb tumor suppressors, respectively. Acting together, E6 and E7 are sufficient to induce transformation in the absence of mutations in cell regulatory proteins. Recall that the HPV E5 protein, which causes sustained activation of the PDGF receptor, enhances proliferation of the transformed cells.

The active form of p53 is a tetramer of four identical subunits. A missense point mutation in one of the two p53 alleles

in a cell can abrogate almost all p53 activity because virtually all the oligomers will contain at least one defective subunit, and such oligomers have reduced ability to activate transcription. Oncogenic *p53* mutations thus act as **dominant negatives**, with mutations in a single allele causing a loss of function. The loss of function is incomplete, so in order to grow more rapidly, tumor cells still sometimes lose the remaining functional allele (loss of heterozygosity). As we learned in Chapter 5, dominant-negative mutations can occur in proteins whose active forms are multimeric or whose function depends on interactions with other proteins. In contrast, loss-of-function mutations in other tumor-suppressor genes (e.g., *RB*) are recessive because the encoded proteins function as monomers and mutation of a single allele has little functional consequence.

The p53 protein is a key defense mechanism against cancerous transformation. This is best illustrated by the high frequency of loss of p53 function in human cancers. Loss-of-function mutations in the *p53* gene occur in more than 50 percent of human cancers. What does it protect us against? Unlike *Rb*, which prevents inappropriate proliferation, p53 guards the cell from genetic changes. When the p53 G₁ checkpoint control does not operate properly, damaged DNA can replicate, perpetuating mutations and DNA rearrangements that are passed on to daughter cells, contributing to the likelihood of transformation into metastatic cells. At the same time, apoptosis is inhibited, contributing to evolution of transformed cells. Because of its central role in preventing tumorigenesis, researchers are intensely searching for compounds that can restore p53 function as a new way of treating a broad spectrum of human tumors.

Apoptotic Genes Can Function as Proto-oncogenes or Tumor-Suppressor Genes

During normal development many cells are designated for **programmed cell death**, also known as apoptosis (see Chapter 21). Many abnormalities, including errors in mitosis, DNA damage, and an abnormal excess of cells not needed for development of a working organ, can trigger apoptosis. In some cases, cell death appears to be the default situation, with signals required to ensure cell survival. Cells can receive instructions to live and instructions to die, and a complex regulatory system integrates the various kinds of information.

If cells do not die when they should and instead keep proliferating, a tumor may form. For example, chronic lymphocytic leukemia (CLL) occurs because cells survive when they should be dying. The cells accumulate slowly, and most are not actively dividing, but they do not die. CLL cells have chromosomal translocations that activate a gene called *bcl-2*, which we now know to be a critical blocker of apoptosis (see Figure 21-37). The resultant inappropriate overproduction of Bcl-2 protein prevents normal apoptosis and allows survival of these tumor cells. CLL tumors are therefore attributable to a failure of cell death. Another dozen or so proto-oncogenes that are normally involved in negatively regulating apoptosis have been mutated to become oncogenes. Overproduction of

their encoded proteins prevents apoptosis even when it is needed to stop cancer cells from growing.

Conversely, genes whose protein products stimulate apoptosis behave as tumor suppressors. An example is the *PTEN* gene discussed in Chapter 16. The phosphatase encoded by this gene dephosphorylates phosphatidylinositol 3,4,5-trisphosphate, a secondary messenger that functions in activation of Akt (see Figure 16-26). Cells lacking PTEN phosphatase have elevated levels of phosphatidylinositol 3,4,5-trisphosphate and active Akt, which promotes cell survival, growth, and proliferation and prevents apoptosis by several pathways. Thus PTEN acts as a pro-apoptotic tumor suppressor by decreasing the anti-apoptotic and proliferation-promoting effects of Akt.

The most common pro-apoptotic tumor-suppressor gene implicated in human cancers is *p53*. Among the genes activated by p53 are several encoding pro-apoptotic proteins such as Bax (see Figure 21-38). When most cells suffer extensive DNA damage or numerous other stresses such as hypoxia, the p53-induced expression of pro-apoptotic proteins leads to their quick demise (see Figure 24-26). While this may seem like a drastic response to DNA damage, it prevents proliferation of cells that are likely to accumulate multiple mutations. When p53 function is lost, apoptosis cannot be induced and the accumulation of mutations required for cancer to develop becomes more likely.

Micro-RNAs Are a New Class of Oncogenic Factors

In the last few years it has become clear that noncoding RNAs, especially micro-RNAs (miRNAs), play a critical role in tumorigenesis. Generation of miRNAs typically involves the transcription of a precursor RNA that, through a number of processing steps, is trimmed down to a 20-22-nucleotide-long mature miRNA. The mature microRNAs usually bind in the 3' untranslated region (UTR) of their target RNAs and inhibit their translation or sometimes cause degradation of the target mRNA. To date, approximately 750 miRNAs have been identified in humans and have been implicated in the regulation of as many as 30 percent of the cell's mRNAs, with fundamental roles in cell proliferation, differentiation, and apoptosis. A number of them have also been shown to function as tumor-suppressor genes or oncogenes.

The first role of miRNAs in tumorigenesis was revealed by the analysis of chromosomal region 13q14.3. This genomic region is found deleted in most cases of chronic lymphocytic leukemia (CLL), the most common leukemia in humans. Characterization of the disease causing deletion showed that two micro-RNAs, miR-15-a and miR-16-1, cause CLL. Mice mutant for both micro-RNAs develop CLL or the related cell lymphocytic leukemia. The two micro-RNAs appear to control cell-proliferation genes. In their absence, proliferation of B cells is increased. The let7 family of miRNAs has also been implicated in tumorigenesis. Let-7 miRNAs down-regulate the translation of Ras. Thus in the absence of the miRNA, Ras is constitutively overproduced, contributing to tumorigenesis. Let-7 miRNAs have other targets in

the cell as well, and it is generally believed that each micro-RNA has multiple targets, providing ample opportunity to contribute to tumorigenesis.

Because of their function in inhibiting translation, miRNAs can function as tumor suppressor genes as well as oncogenes. miR-15-a and miR-16-1 act as tumor-suppressor genes; they normally inhibit cell proliferation, and their absence leads to cell growth. However, some miRNAs have also been found to be overexpressed in cancer, and their analysis indicates they function as oncogenes. Overexpression of miR-155 is found in many cancers and causes expansion of large B cells. Of particular interest is miR-21. This micro-RNA is overexpressed in most solid tumors, including glioblastoma, breast, lung, pancreatic, and colon tumors, and it targets several tumor-suppressor genes, among them the PTEN phosphatase. Much needs to be learned about how micro-RNAs contribute to tumorigenesis, but it is clear that through their ability to regulate many different genes, they can impact disease progression in more than one way.

KEY CONCEPTS of Section 24.4

Cancer and Mutation of Cell Division and Checkpoint Regulators

- Overexpression of the proto-oncogene encoding cyclin D1 or loss of the tumor-suppressor genes encoding p16 and Rb can cause inappropriate, unregulated passage through START in late G₁. Such abnormalities are seen in 80 percent of human tumors.
- The INK4-ARF locus represents the major tumor-suppressor locus in humans, controlling both the Rb and p53 pathways (see Figure 24-25).
- The p53 protein is a multifunctional tumor suppressor that promotes arrest in G₁ and G₂, apoptosis, and DNA repair in response to damaged DNA (see Figure 24-26).
- Loss-of-function mutations in the p53 gene occur in more than 50 percent of human cancers. Overproduction of Mdm2, a protein that normally inhibits the activity of p53, occurs in several cancers (e.g., sarcomas) that express normal p53 protein. Thus in one way or another, the p53 stress-response pathway is inactivated to allow tumor growth.
- Human papillomavirus (HPV) encodes three oncogenic proteins: E6 (inhibits p53), E7 (inhibits Rb), and E5 (activates the PDGF receptor).
- Overproduction of anti-apoptotic proteins (e.g., Bcl-2) can lead to inappropriate cell survival and is associated with chronic lymphoblastic leukemia (CLL) and other cancers. Loss of proteins that promote apoptosis (e.g., p53 transcription factor and PTEN phosphatase) have a similar oncogenic effect.
- Micro-RNAs have been implicated in disease progression in many different types of cancer. They can function as tumor suppressors or as oncogenes.

24.5 Carcinogens and Caretaker Genes in Cancer

Carcinogens, which can be natural or man-made, are chemicals that cause cancer. Carcinogens cause mutations that reduce the function of tumor-suppressor genes, create oncogenes from proto-oncogenes, or damage DNA-repair systems. As our previous discussion has shown, alterations in DNA that lead to malfunction of tumor-suppressor proteins and oncoproteins are the underlying cause of most cancers. These oncogenic mutations in key growth and cell cycle regulatory genes include insertions, deletions, and base substitutions as well as chromosomal amplifications and translocations. In addition, damage to caretaker genes comprising the DNA-repair systems (see Chapter 4) leads to an increased mutation rate. Of the many mutations that accumulate, some affect cell cycle regulators, and the cells bearing these may become cancerous. Furthermore, some DNA-repair mechanisms themselves are error prone (see Figure 4-40). Those “repairs” also contribute to oncogenesis. The inability of tumor cells to maintain genomic integrity leads to formation of a heterogeneous population of malignant cells. For this reason, chemotherapy directed toward a single gene or even a group of genes is likely to be ineffective in wiping out all malignant cells. This problem adds to the interest in therapies that interfere with the blood supply to tumors, target aneuploid cells, or in other ways act on multiple types of tumor cells.

Normal dividing cells usually employ several mechanisms to prevent accumulation of detrimental mutations that could lead to cancer. One form of protection against mutation for stem cells is their relatively low rate of division, which reduces the possibility of DNA damage incurred during DNA replication and mitosis. Furthermore, the progeny of stem cells do not have the ability to divide indefinitely. After several rounds of division they exit the cell cycle, reducing the possibility of mutation-induced misregulation of cell division associated with dangerous tumors. Also, if multiple mutations are required for a tumor to grow, attract a blood supply, invade neighboring tissues, and metastasize, a low rate of replication combined with the normal low rate of mutations (10^{-9}) provides further shielding from cancer. However, these safeguards can be overcome if a powerful mutagen reaches the cells or if DNA repair is compromised and the mutation rate rises. When cells with stem-cell-like growth properties are mutagenized by environmental poisons and unable to efficiently repair the damage, cancer can occur.

In this section, we explore the ways in which various carcinogens act on DNA to induce cancer as well as how mutations in caretaker genes contribute to cancer by compromising the cell's ability to repair DNA damage. We end the chapter with a discussion of a special enzyme called telomerase, another guardian of the genome that protects against DNA damage, and its role in cancer cells.

Carcinogens Induce Cancer by Damaging DNA

The ability of chemical and physical carcinogens to induce cancer is due to the DNA damage that they cause as well as

the errors introduced into DNA during the cells' efforts to repair this damage. Thus carcinogens also are **mutagens**. The strongest evidence that carcinogens act as mutagens comes from the observation that cellular DNA altered by exposure of cells to carcinogens can change cultured cells, such as 3T3 cells, or cells implanted in mice into fast-growing cancer-like cells (see Figure 24-4). The mutagenic effect of carcinogens is roughly proportional to their ability to transform cells and induce cancer in animal models.

Although substances identified as chemical carcinogens have a broad range of structures with no obvious unifying features, they can be classified into two general categories. *Direct-acting carcinogens*, of which there are only a few, are mainly reactive electrophiles (compounds that seek out and react with electron-rich centers in other compounds). By chemically reacting with nitrogen and oxygen atoms in DNA, these compounds can modify bases in DNA so as to distort the normal pattern of base pairing. If these modified nucleotides are not repaired, they allow an incorrect nucleotide to be incorporated during replication. This type of carcinogen includes ethylmethane sulfonate (EMS), dimethyl sulfate (DMS), and nitrogen mustards.

In contrast, *indirect-acting carcinogens* generally are unreactive, often water-insoluble compounds that can act as potent cancer inducers only after the introduction of electrophilic centers. In animals, *cytochrome P-450 enzymes* are located in the endoplasmic reticulum of most cells and at especially high levels in liver cells. P-450 enzymes normally function to add electrophilic centers, such as OH groups, to nonpolar foreign chemicals, such as certain insecticides and therapeutic drugs, in order to solubilize them so that they can be excreted from the body. However, P-450 enzymes also can turn otherwise harmless chemicals into carcinogens. Indeed, most chemical carcinogens have little mutagenic effect until they have been modified by cellular enzymes.

Some Carcinogens Have Been Linked to Specific Cancers

In the earliest days of cancer awareness, it became clear that at least some cancers are due to environmental poisons. For example, in 1775 it was reported that the exposure of chimney sweeps to soot caused scrotal cancer, and in 1791 the use of snuff (tobacco) was reported to be associated with nasal cancer. Environmental chemicals were originally associated with cancer through experimental studies in animals. The classic experiment is to repeatedly paint a test substance on the back of a mouse and look for development of both local and systemic tumors in the animal. Such assays led to the purification of a pure chemical carcinogen from coal tar in 1933, benzo(a)pyrene. The role of radiation in damaging chromosomes was first demonstrated in the 1920s using x-irradiated *Drosophila*. Later the ability of radiation to cause human cancer, especially leukemia, was dramatically shown by the increased rates of leukemia among survivors of the atomic bombs dropped in World War II (ionizing radiation)

FIGURE 24-27 Chemical carcinogenesis by tobacco smoke.

Cigarette smoking provides a clear example of a deadly form of chemical carcinogenesis. The rates of lung cancer follow the rates of smoking, with about a 30-year lag. Women began to smoke in large numbers starting in the 1960s, and starting in the 1990s, lung cancer passed breast cancer as the leading cause of women's cancer deaths. At the same time a gradual decrease in smoking rates among men starting in the 1960s has been reflected in a decrease in their lung cancer rate. [From the American Cancer Society.]

and more recently by the increase in melanoma (skin cancer) in individuals exposed to too much sunlight (UV radiation).

Although chemical carcinogens are believed to be risk factors for many human cancers, a direct linkage to specific cancers has been established only in a few cases, the most important being lung cancer and the other cancers (laryngeal, pharynx, stomach, liver, pancreas, bladder, cervix, and more) that are associated with smoking. Epidemiological studies (Figure 24-27) first indicated that cigarette smoking was the major cause of lung cancer, but the reason was unclear until the discovery that about 60 percent of human lung cancers contain inactivating mutations in the *p53* gene. The chemical benzo(a)pyrene, found in cigarette smoke as well as coal tar, undergoes metabolic activation in the lung (Figure 24-28) to a potent mutagen that mainly causes conversion of guanine (G) to thymine (T) bases, a transversion mutation. When applied to cultured bronchial epithelial cells, activated benzo(a)pyrene induces many mutations, including inactivating mutations at codons 175, 248, and 273 of the *p53* gene. These same positions, all within the protein's DNA-binding domain, are major mutational hot spots in human lung cancer. In fact, the nature of mutations in *p53* (and other cancer-related genes) gives clues as to the origin of the cancer. The G-to-T transversions caused by benzo(a)pyrene, for example, are present in the *p53* genes of about one-third of smokers' lung tumors. That type of mutation is relatively rare among the *p53* mutations found in other types of tumors. The carcinogen leaves its footprint. Thus there is a strong correlation between one defined chemical carcinogen in cigarette smoke and human cancer. It is likely that other chemicals in cigarette smoke induce mutations in other genes since it contains

FIGURE 24-28 Enzymatic processing of benzo(a)pyrene to a more potent mutagen and carcinogen. Liver enzymes, particularly P-450 enzymes, modify benzo(a)pyrene in a series of reactions, producing 7,8-diol-9,10-epoxide, a highly potent mutagenic species that reacts with DNA primarily at the N₂ atom of a guanine base in DNA. The resulting adduct, (+)-trans-anti-B(a)P-N²-dG, causes polymerase to insert an A rather than a C opposite the modified G base. Next time the

DNA is replicated, a T will be inserted opposite the A, and the mutation will be complete. Horizontal arrows indicate alterations toward greater potency, while vertical arrows indicate changes in the direction of reduced toxicity. The large "O" symbol represents the rest of the multi-ring structure shown in the complete benzo(a)pyrene molecule at the left. [Adapted from E. L. Loechler, 2001, *Encyclopedia of Life Science*.]

more than 60 carcinogens. Similarly, asbestos exposure is clearly linked to mesothelioma, a type of epithelial cancer.

Lung cancer is not the only major human cancer for which a clear-cut risk factor has been identified. *Aflatoxin*, a fungal metabolite found in moldy grains, induces liver cancer (Figure 24-29a). After chemical modification by liver enzymes, aflatoxin becomes linked to G residues in DNA and induces G-to-T transversions. Aflatoxin also causes a mutation in the *p53* gene. Furthermore, cooking meat at high temperatures causes chemical reactions that form *heterocyclic amines* (HCAs), which are potent mutagens and cause colon and breast carcinomas in animal models. HCAs react with deoxyguanosine bases to form mutagenic adducts (Figure 24-29b). Exposure to other chemicals has been correlated with minor cancers. Hard evidence concerning dietary and environmental risk factors that would help us avoid other common cancers (e.g., breast, colon, and prostate cancer and leukemias) is generally lacking.

Loss of DNA-Repair Systems Can Lead to Cancer

Even without any external carcinogen or mutagen, normal processes generate a large amount of DNA damage. The damage is due to depurination reactions, to alkylation reactions, and to the generation of reactive species such as oxygen radicals, all of which alter DNA. It has been estimated that in every cell, more than 20,000 alterations to the DNA

occur each day from just reactive oxygen species and depurination. Thus DNA repair is a crucial defense system.

The normal role of caretaker genes is to prevent or repair DNA damage. Loss of the high-fidelity DNA-repair systems that are described in Chapter 4 correlates with increased risk for cancer. For example, humans who inherit mutations in genes that encode a crucial mismatch-repair or excision-repair protein have an enormously increased probability of developing certain cancers (Table 24-2). Without proper DNA repair, people with xeroderma pigmentosum (XP) or hereditary non-polyposis colorectal cancer (HNPCC, also known as Lynch syndrome) have a propensity to accumulate mutations in many other genes, including those that are critical in controlling cell growth and proliferation. XP causes affected people to develop skin cancer at about a thousand times the normal rate. Seven of the eight known XP genes encode components of the excision-repair machinery, and in the absence of this repair mechanism, genes that control the cell cycle or otherwise regulate cell growth and death become mutated. HNPCC genes encode components of the mismatch-repair system, and mutations in these genes are found in 20 percent of sporadic colon cancers. The cancers progress from benign polyps to full-fledged tumors much more rapidly than usual, presumably because the initial cancer cells are undergoing continuous mismatch mutagenesis without repair.

One gene frequently mutated in colon cancers because of the absence of mismatch repair encodes the type II receptor for

FIGURE 24-29 Actions of two chemical carcinogens. (a) Like all indirect-acting carcinogens, aflatoxin must undergo enzyme-catalyzed modification before it can react with DNA. In aflatoxin the colored double bond reacts with an oxygen atom, enabling it to react chemically with the N-7 atom of a guanine in DNA, forming a large bulky molecule that causes DNA polymerase to insert an A rather than a C opposite the modified G base during replication. This compound mutates the *p53* tumor-suppressor gene, causing G to T transversions, and is a known risk factor for human cancer. (b) Chemical reactions that occur in human food raised to high temperature, especially red meat, create about 16 different types of heterocyclic amines (HCAs) from precursors such as creatine and amino acids. The HCA shown here, PhIP, is the most common one in the human diet. Cytochrome P-450 enzymes convert it to a very chemically reactive form, which reacts with a guanine base in DNA to form a DNA adduct that is mutagenic. PhIP causes breast and colon carcinomas in rodents and may be involved in human prostate cancer. Although the P-450 conversions occur mainly in liver cells, the HCAs can migrate to other tissues.

TGF- β (see Figure 24-23). The gene encoding this receptor contains a sequence of 10 adenines in a row. Because of “slippage” of DNA polymerase during replication, this sequence often undergoes mutation to a sequence containing 9 or 11 adenines. If the mutation is not fixed by the mismatch-repair system, the resultant frameshift in the protein-coding sequence abolishes production of the normal receptor protein. As noted earlier, such inactivating mutations make cells resistant to growth inhibition by TGF- β , thereby contributing to the unregulated growth characteristic of these tumors. This finding attests to the importance of mismatch repair in correcting genetic damage that might otherwise lead to uncontrolled cell proliferation.

All DNA-repair mechanisms utilize a family of DNA polymerases to correct DNA damage. Nine of these polymerases, including one called *DNA polymerase β* , are capable of using templates that contain DNA adducts and other chemical mod-

ifications, even missing bases. These are called *lesion-bypass* DNA polymerases. Each member of the polymerase family has distinct capabilities to cope with particular types of DNA lesions. Presumably such polymerases are tolerated because often any repair is better than none. They are the polymerases of last resort, the ones used when more conventional and accurate polymerases are unable to perform, and they carry out a mutagenic replication process. DNA Pol β does not proof-read and is overexpressed in certain tumors, perhaps because it is needed at high levels for cells to be able to divide at all in the face of a growing burden of mutations. Error-prone repair systems are thought to mediate much, if not all, of the carcinogenic effects of chemicals and radiation since it is only after the repair that a heritable mutation exists. There is growing evidence that mutations in DNA Pol β are associated with tumors. When 189 tumors were examined, 58 had mutations

TABLE 24-2 Some Human Hereditary Diseases and Cancers Associated with DNA-Repair Defects

Disease	DNA-Repair System Affected	Sensitivity	Cancer Susceptibility	Symptoms
PREVENTION OF POINT MUTATIONS, INSERTIONS, AND DELETIONS				
Hereditary nonpolyposis colorectal cancer	DNA mismatch repair	UV irradiation, chemical mutagens	Colon, ovary	Early development of tumors
Xeroderma pigmentosum	Nucleotide excision repair	UV irradiation, point mutations	Skin carcinomas, melanomas	Skin and eye photosensitivity, keratoses
REPAIR OF DOUBLE-STRAND BREAKS				
Bloom's syndrome	Repair of double-strand breaks by homologous recombination	Mild alkylating agents	Carcinomas, leukemias, lymphomas	Photosensitivity, facial telangiectases, chromosome alterations
Fanconi anemia	Repair of double-strand breaks by homologous recombination	DNA cross-linking agents, reactive oxidant chemicals	Acute myeloid leukemia, squamous-cell carcinomas	Developmental abnormalities including infertility and deformities of the skeleton; anemia
Hereditary breast cancer, BRCA-1 and BRCA-2 deficiency	Repair of double-strand breaks by homologous recombination		Breast and ovarian cancer	Breast and ovarian cancer

SOURCES: Modified from A. Kornberg and T. Baker, 1992, *DNA Replication*, 2d ed., W. H. Freeman and Company, p. 788; J. Hoeijmakers, 2001, *Nature* 411:366; and L. Thompson and D. Schild, 2002, *Mutation Res.* 509:49.

in the DNA Pol β gene, and most of these mutations were found neither in normal tissue from the same patient nor in the normal spectrum of mutations found in different people. Expressing two of the mutant polymerase forms in mouse cells caused them to grow with a transformed appearance, with focus formation and anchorage independence.

Double-strand breaks are particularly severe lesions because incorrect rejoining of double strands of DNA can lead to gross chromosomal rearrangements and translocations such as those that produce a hybrid gene or bring a growth regulatory gene under the control of a different promoter. Often the repair of such damage depends on using the homologous chromosome as a guide (see Figure 4-42). The B and T cells of the immune system are particularly susceptible to DNA rearrangements caused by double-strand breaks created during rearrangement of their immunoglobulin or T-cell receptor genes, explaining the frequent involvement of these gene loci in leukemias and lymphomas. *BRCA-1* and *BRCA-2*, genes implicated in human breast and ovarian cancers, encode important components of DNA-break repair systems. Cells lacking one of the *BRCA*

functions are unable to repair DNA where the homologous chromosome is providing the template for repair.

Telomerase Expression Contributes to Immortalization of Cancer Cells

Telomeres, the physical ends of linear chromosomes, consist of tandem arrays of a short DNA sequence, TTAGGG in vertebrates. Telomeres provide the solution to the end-replication problem—the inability of DNA polymerases to completely replicate the end of a double-stranded DNA molecule (see Chapter 6). *Telomerase*, a reverse transcriptase that contains an RNA template, repeatedly adds TTAGGG repeats to chromosome ends to lengthen or maintain the 3- to 20-kb regions of repeats that decorate the ends of human chromosomes (see Figure 6-47). Embryonic cells, germ-line cells, and stem cells produce telomerase, but most human somatic cells produce only a low level of telomerase as they enter S phase. As a result of having only modest telomerase function, their telomeres shorten with each cell cycle. Extensive shortening of telomeres is recognized

FIGURE 24-30 Loss of telomeres normally limits the number of rounds of cell division. Replication of the ends of chromosomes, the telomeres, requires a special enzyme called *telomerase*. Telomerase carries with it a short RNA template, which is used to guide the assembly of repeats of TTAGGG on the ends of chromosomes. Human embryonic cells have 8–10 kb of these repeats on each chromosome end. Because DNA polymerase requires a primer and there is none at the end of the lagging strand, it cannot replicate DNA fully at the ends (see Chapter 6). Telomerase is therefore necessary, and in its absence chromosomes shrink during each mitosis. Telomerase is present in stem cells and germ-line cells, where it is needed to keep telomeres long and allow essentially indefinite rounds of cell division. In most somatic cells, telomerase is at low or very low levels, and the length of telomeres is consequently gradually eroded. The length of the telomeres therefore provides one limit to replicative capacity. Complete loss of telomere repeats leads to triggering of DNA repair and apoptosis. Cancer cells often produce telomerase, allowing them to divide indefinitely and evade programmed death.

by the cell as a kind of DNA damage, with consequent stabilization and activation of p53 protein, leading to p53-triggered apoptosis. Figure 24-30 summarizes the effects of different numbers of telomere repeats. Complete loss of telomeres leads to end-to-end chromosome fusions and cell death.

Most tumor cells, despite their rapid proliferation rate, overcome this fate by producing telomerase. Many researchers believe that telomerase expression is essential for a tumor cell to become immortal, and specific inhibitors of telomerase have been suggested as cancer therapeutic agents. Introduction of telomerase-producing transgenes into cultured human cells that otherwise lack the enzyme can extend their life span by more than 20 doublings while maintaining telomere length. Conversely, treating human tumor cells (HeLa cells) in culture with antisense RNA against telomerase caused them to cease growth in about four weeks. Dominant-negative telomerases, such as those carrying a modified RNA template, can interfere with cancer cell growth.

The prognosis for neuroblastoma, a pediatric tumor of the peripheral nervous system, can be ascertained by assessing the level of telomerase activity in tumor cells. High levels of telomerase predict a poor response to therapy, while low levels predict a good response. The level of *N-myc* protein, a transcription factor that regulates expression of telomerase, is also predictive for the outcomes of these tumors. Tumors that have amplified the *N-myc* gene to high copy number have a worse prognosis. These results show the practical importance of understanding the circuitry of telomere synthesis and its regulation. ■

Genetic approaches have further improved our understanding of the role of telomerase in cancer. The initial finding that mice homozygous for a deletion of the RNA subunit of telomerase are viable and fertile was surprising. However, after four to six generations defects began to appear in the telomerase-null mice as their very long telomeres (40–60 kb) became significantly shorter. The defects included depletion of tissues that require high rates of cell division, such as skin and intestine, and infertility.

When treated with carcinogens, telomerase-null mice develop tumors less readily than normal mice do. For example, skin papillomas induced by a combination of chemical carcinogens occur 20 times less frequently in mice lacking a functional telomerase than in normal mice, presumably because p53-triggered apoptosis is induced in response to the ever-shortening telomeres of cells that have begun to divide. However, if both telomerase and p53 are absent, there is an increased rate of epithelial tumors such as squamous-cell carcinoma, colon, and breast cancer. Mice with an APC mutation normally develop colon tumors, and these too are reduced if the mice lack telomerase. Some other tumors are less affected by loss of telomerase. These studies demonstrate the relevance of telomerase for unbridled cell division and make the enzyme a possible target for chemotherapy.

KEY CONCEPTS of Section 24.5

Carcinogens and Caretaker Genes in Cancer

- Changes in the DNA sequence result from copying errors and the effects of various physical and chemical agents, or carcinogens. All carcinogens are mutagens; that is, they alter one or more nucleotides in DNA.
- Indirect-acting carcinogens, the most common type, must be activated before they can damage DNA. In animals, metabolic activation occurs via the cytochrome P-450 system, a pathway generally used by cells to rid themselves of noxious foreign chemicals. Direct-acting carcinogens such as EMS and DMS require no such cellular modifications in order to damage DNA.
- Benzo(a)pyrene, a component of cigarette smoke, causes inactivating mutations in the *p53* gene, thus contributing to the initiation of human lung tumors.

- Caretaker genes encode enzymes that repair DNA, otherwise maintain the integrity of the chromosomes, or promote the death of cells when DNA damage does occur. Mutations in caretaker genes allow the survival of cells that should die and a continuing mutagenesis of the genome that can lead to uncontrolled cell proliferation and hence cancer.
- Inherited defects in DNA-repair processes found in certain human diseases are associated with an increased susceptibility for certain cancers (see Table 24-2).
- Cancer cells, like germ cells and stem cells but unlike most differentiated cells, produce telomerase, which prevents shortening of chromosomes during DNA replication and may contribute to their immortalization. The absence of telomerase is associated with resistance to generation of certain tumors, owing to the protective p53 response.

Perspectives for the Future

The recognition that cancer is fundamentally a genetic disease has opened enormous new opportunities for preventing and treating it. Carcinogens can now be assessed for their effects on known steps in cell cycle control. Genetic defects in the checkpoint controls for detecting damaged DNA and in the systems for repairing it can be readily recognized and used to explore the mechanisms of cancer. The multiple changes that must occur for a cell to grow into a dangerous tumor present multiple opportunities for intervention. Identifying mutated genes associated with cancer points directly toward proteins to which drugs can be targeted.

Diagnostic medicine is being transformed by our newfound ability to monitor large numbers of cell characteristics and by ever more sensitive methods to detect smaller numbers of tumor cells. The traditional methods of assessing possible tumor cells, mainly microscopy of stained cells, will be augmented or replaced by techniques for measuring the expression of tens of thousands of genes, focusing particularly on genes whose activities are identified as powerful indicators of the cell's growth properties and the patient's prognosis. Currently, DNA microarray and deep-sequencing analyses permit measurement of gene transcription and DNA copy number. In the future, techniques for systematically measuring protein content as well as proteins' modifications and localization, all important measures of cell states, will give us even more refined portraits of cells. Tumors now viewed as identical or very similar will instead be recognized as distinctly different and given appropriately different treatments. Earlier detection of tumors, based on better monitoring of cell properties, should allow more successful treatment. A focus on that particularly destructive process metastasis should be successful in identifying more of the mechanisms used by cells to migrate, attach, and invade. Manipulation of angiogenesis continues to look hopeful as a means of suffocating tumors.

The molecular cell biology of cancer provides avenues for new therapies, but prevention remains crucial and preferable to

therapy. Avoidance of obvious carcinogens, in particular cigarette smoke, can significantly reduce the incidence of lung cancer and perhaps other kinds of cancer as well. Beyond minimizing exposure to carcinogens such as smoke or sunlight, certain specific approaches are now feasible. New knowledge of the involvement of human papillomavirus 16 in most cases of cervical cancer led to the development and Federal Drug Administration approval of a cancer vaccine that prevents three-quarters of all cervical cancers. Antibodies against cell-surface markers that distinguish cancer cells are a source of great hope, especially after successes with the clinical use of monoclonal antibodies against human EGF receptor 2 (Her2), a protein involved in some cases of human breast cancer. Further steps must involve medicine and science. Understanding the cell biology of cancer is a critical first step toward prevention and cure, but the next steps are hard. The success with Gleevec (imatinib) against leukemia is exceptional; many cancers remain difficult to treat and cause enormous suffering. Since *cancer* is a term for a group of highly diverse diseases, interventions that are successful for one type may not be useful for others. Despite these daunting realities, we are beginning to reap the benefits of decades of research exploring the molecular biology of the cell. We hope that many of the readers of this book will help to overcome the obstacles that remain.

Key Terms

angiogenesis 1117	oncogene addiction 1132
benign 1115	p53 protein 1122
Burkitt's lymphoma 1136	Philadelphia
cancer stem cell 1116	chromosome 1135
carcinogen 1113	proto-oncogene 1113
carcinoma 1115	Ras protein 1118
caretaker gene 1113	retinoblastoma (Rb)
epithelial-to-mesenchymal	protein 1128
transition (EMT) 1116	sarcoma 1115
leukemia 1115	slow-acting retrovirus 1127
loss of heterozygosity	transducing retrovirus 1127
(LOH) 1129	transformation 1118
malignant 1115	tumorigenesis 1114
metastasis 1114	tumor microenvironment
multi-hit model of	1117
cancer induction 1120	tumor-suppressor
mutagen 1145	gene 1113
oncogene 1113	Warburg effect 1122

Review the Concepts

1. What characteristics distinguish benign from malignant tumors? With respect to gene mutations, what distinguishes benign colon polyps from malignant colon carcinoma?
2. Ninety percent of cancer deaths are caused by metastatic rather than primary tumors. Define *metastasis*. Explain the

rationale for the following new cancer treatments: (a) batimastat, an inhibitor of matrix metalloproteinases and of the plasminogen activator receptor, (b) antibodies that block the function of integrins, integral membrane proteins that mediate attachment of cells to the basement membrane and extracellular matrices of various tissues, and (c) bisphosphonate, which inhibits the function of osteoclasts. Osteoclasts are cells that digest bones, for example, in remodeling during growth or healing. They can be recruited to a bone-digesting task by signals from other cells. (d) What is the importance of the EMT during metastasis?

3. Because of oxygen and nutrient requirements, cells in a tissue must reside within 100 μm of a blood vessel. Based on this information, explain why many malignant tumors often possess gain-of-function mutations in one of the following genes: *βFGF*, *TGFα*, and *VEGF*.

4. *Ras* oncogenes have been identified in human tumor cells using cell transformation assays with a line of cultured mouse fibroblasts called 3T3 cells. How does the 3T3 cell transformation assay work? Why can transfection with a *ras* gene transform 3T3 cells but not normal cultured primary fibroblast cells?

5. Which important characteristic of tumor cells did Otto Warburg discover? How does this property contribute to the process of tumor formation?

6. What hypothesis explains the observations that incidence of human cancers increases exponentially with age? Give an example of data that confirm the hypothesis.

7. Distinguish between proto-oncogenes and tumor-suppressor genes. To become cancer promoting, do proto-oncogenes and tumor-suppressor genes undergo gain-of-function or loss-of-function mutations? Classify the following genes as proto-oncogenes or tumor-suppressor genes: *p53*, *ras*, *Bcl-2*, *jun*, *MDM2*, and *p16*.

8. Explain how DNA microarray analysis can diagnose the outcome of early stage breast cancer.

9. Despite differences in origin, cancer cells have several features in common that differentiate them from normal cells. Describe these.

10. Hereditary retinoblastoma generally affects children in both eyes, while spontaneous retinoblastoma usually occurs during adulthood only in one eye. Explain the genetic basis for the epidemiological distinction between these two forms of retinoblastoma. Explain the apparent paradox: loss-of-function mutations in tumor-suppressor genes act recessively, yet hereditary retinoblastoma is inherited as an autosomal dominant.

11. Explain the concept of loss of heterozygosity (LOH). Why do most cancer cells exhibit LOH of one or more genes? How does failure of the spindle assembly checkpoint lead to loss of heterozygosity?

12. Many malignant tumors are characterized by the activation of one or more growth-factor receptors. What is the catalytic activity associated with transmembrane growth-factor receptors such as the EGF receptor? Describe how the following events lead to activation of the relevant growth-factor receptor: (a) expression of the viral protein gp55,

(b) point mutation that converts a valine to glutamine within the transmembrane region of the Her2 receptor.

13. Describe the common signal transduction event that is perturbed by cancer-promoting mutations in the genes encoding Ras and NF-1. Why are mutations in Ras more commonly found in cancers than mutations in NF-1?

14. What is the structural distinction between the proteins encoded by *c-src* and *v-src*? How does this difference render *v-src* oncogenic?

15. Describe the mutational event that produces the *myc* oncogene in Burkitt's lymphoma. Why does the particular mechanism for generating oncogenic *myc* result in a lymphoma rather than another type of cancer? Describe another mechanism for generating oncogenic *myc*.

16. Pancreatic cancers often possess loss-of-function mutations in the gene that encodes the Smad4 protein. How does this mutation promote the loss-of-growth inhibition and highly metastatic phenotype of pancreatic tumors?

17. Why are mutations in the INK4 locus so dangerous?

18. Describe two mechanisms through which cancer-causing viruses can transform normal cells into cancer cells.

19. Explain how epigenetic changes can contribute to tumorigenesis.

20. Several strains of human papilloma virus (HPV) can cause cervical cancer. These pathogenic strains produce three proteins that contribute to host-cell transformation. What are these three viral proteins? Describe how each interacts with its target host protein.

21. Loss of p53 function occurs in the majority of human tumors. Name two ways in which loss of p53 function contributes to a malignant phenotype. Explain how benzo(a)pyrene can cause loss of p53 function.

22. Which human cell types possess telomerase activity? What characteristic of cancer is promoted by expression of telomerase? What concerns does this pose for medical therapies involving stem cells?

Analyze the Data

1. Cigarette smoking is a major risk factor in the development of non-small-cell lung cancer (NSCLC), which accounts for 80 percent of all lung cancers. NSCLC is characterized by poor prognosis and resistance to chemotherapy. To understand if nicotine affects this resistance, lung cancer cell lines were treated with the chemotherapeutic drugs gemcitabine, Cisplatin, and Taxol in the presence and absence of nicotine (see Dasgupta et al., 2006, *Proc. Nat'l. Acad. Sci. USA* 103:6332–6337).

a. Three different NSCLC cell lines, A549, NCI-H23, and H1299, were examined by the TUNEL assay, which detects cells that are undergoing apoptosis (programmed cell death). The cells were either untreated or treated with one of the three chemotherapeutic drugs in the presence or absence of nicotine. The following data were obtained. Why are these

chemotherapeutic drugs potentially useful for the treatment of lung cancer, and how does nicotine affect their potential usefulness?

b. A549 cells were incubated with the drugs as in part (a) and an additional chemotherapeutic drug, camptothecin, in the presence or absence of nicotine. The cells were lysed, extracts were run on SDS gels, and then the gels were blotted and probed with antibodies against the indicated proteins. PARP is a protein that is cleaved during apoptosis. What can you deduce from these data about the effects of nicotine? What is the purpose of assessing the levels of p53, p21, and actin?

c. Survivin and XIAP are both members of the inhibitor-of-apoptosis (IAP) family, proteins that protect cells against apoptosis. A549 cells were treated with the chemotherapeutic drugs in the presence or absence of nicotine and presence or absence of LY294002, an inhibitor of PI-3 kinase (see Chapter 16). The levels of PARP, XIAP, survivin, and actin were assessed, as

shown in the Western blots below. The graph shows the results of a TUNEL assay in which A549 cells have been transfected with the indicated siRNAs. “None” indicates the amount of cell death with no transfected RNA. Control siRNAs 1 and 2 are irrelevant RNAs added to control for nonspecific effects of having an interfering RNA entering the cells. What do these studies suggest about the mechanism of nicotine action?

d. Can you provide a biological explanation for why the prognosis is poorer for patients who smoke during chemotherapy compared with those who quit smoking prior to it? 2. The E7 oncoprotein of the high-risk human papillomaviruses (HPV) is thought to contribute to cervical carcinogenesis at least in part by disrupting regulation of the cell cycle

in cervical epithelial cells. E7 can dysregulate the cell cycle through its interaction with several cellular proteins, including the retinoblastoma suppressor protein pRb as well as the cyclin-dependent kinase inhibitor p21(Cip1).

a. How can transgenic mouse models be utilized to assess the impact of p21 on cell cycle dysregulation?

b. If the incidence of cervical disease were significantly increased in p21(−/−) mice compared with p21(+ / +) mice, would this support a gain-of-function or loss-of-function role for p21 in the development of cervical cancers?

c. If the ability of E7 to induce cervical cancers were not significantly enhanced on the p21-null background, is this consistent with the hypothesis that the ability of E7 to inhibit p21 contributes to its carcinogenic properties?

d. Explain how expression of E7 mutant proteins in mouse models of cervical cancer can be utilized to assess the impact of these mutations on p21 and development of cervical carcinomas.

GLOSSARY

Boldface terms within a definition are also defined in this glossary. Figures and tables that illustrate defined terms are noted in parentheses.

AAA ATPase family A group of proteins that couple hydrolysis of ATP with large molecular movements usually associated with unfolding of protein substrates or the disassembly of multisubunit protein complexes.

ABC superfamily A large group of integral membrane proteins that often function as ATP-powered **membrane transport proteins** to move diverse molecules (e.g., phospholipids, cholesterol, sugars, ions, peptides) across cellular membranes. (Figure 11-15)

acetylcholine (ACh) Neurotransmitter that functions at vertebrate neuromuscular junctions and at various neuron-neuron synapses in the brain and peripheral nervous system. (Figure 22-19)

acetyl CoA Small, water-soluble metabolite comprising an acetyl group linked to coenzyme A (CoA). The acetyl group is transferred to citrate in the **citric acid cycle** and is used as a carbon source in the synthesis of fatty acids, steroids, and other molecules. (Figure 12-9)

acid Any compound that can donate a proton (H^+). The carboxyl and phosphate groups are the primary acidic groups in biological macromolecules.

actin Abundant structural protein in eukaryotic cells that interacts with many other proteins. The monomeric globular form (*G-actin*) polymerizes to form actin filaments (*F-actin*). In muscle cells, F-actin interacts with **myosin** during contraction. See also **microfilament**. (Figure 17-5)

action potential Rapid, transient, all-or-none electrical activity propagated in the plasma membrane of excitable cells (e.g., neurons and muscle cells) as the result of the selective opening and closing of voltage-gated Na^+ and K^+ channels. (Figures 22-2 and 22-9)

activation domain A region of an activator transcription factor that will stimulate transcription when fused to a DNA-binding domain.

activation energy The input of energy required to (overcome the barrier to) initiate a chemical reaction. By reducing the activation energy, an **enzyme** increases the rate of a reaction. (Figure 2-30)

activator Specific **transcription factor** that stimulates transcription.

active site Specific region of an enzyme that binds a **substrate** molecule(s) and promotes a chemical change in the bound substrate. (Figure 3-21)

active transport Protein-mediated movement of an ion or small molecule across a membrane against its concentration gradient or electrochemical gradient driven by the coupled hydrolysis of ATP. (Figure 11-2, [1]; Table 11-1)

adapter proteins Adapter proteins physically link one protein to another protein by binding to both of them. Adapter proteins directly or indirectly (via additional adapters) connect cell-adhesion molecules or adhesion receptors to elements of the cytoskeleton or to intracellular signaling proteins.

adenosine triphosphate (ATP) See **ATP**.

adenylyl cyclase One of several enzymes that is activated by binding of certain ligands to their cell-surface receptors and catalyzes formation of **cyclic AMP (cAMP)** from ATP; also called *adenylate cyclase*. (Figures 15-27 and 15-28)

adhesion receptor Protein in the plasma membrane of animal cells that binds components of the **extracellular matrix**, thereby mediating cell-matrix adhesion. The **integrins** are major adhesion receptors. (Figure 20-1, [5])

ADP (adenosine diphosphate) The product, along with inorganic phosphate, of ATP hydrolysis by ATPases.

aerobic Referring to a cell, organism, or metabolic process that utilizes gaseous oxygen (O_2) or that can grow in the presence of O_2 .

aerobic oxidation Oxygen-requiring metabolism of sugars and fatty acids to CO_2 and H_2O coupled to the synthesis of ATP.

aerobic respiration See **aerobic oxidation**.

afferent neurons Nerves that transmit signals from peripheral tissues to the central nervous system.

agonist A molecule, often synthetic, that mimics the biological function of a natural molecule (e.g., a hormone).

Agrin A glycoprotein synthesized by developing motor neurons that increases MuSK kinase activity in a muscle cell, facilitating development of a neuromuscular junction. (Figure 22-17)

Akt A cytosolic serine/threonine kinase that is activated following binding to PI 3,4-bisphosphate and PI 3,4,5-trisphosphate; also called *protein kinase B*.

allele One of two or more alternative forms of a gene. Diploid cells contain two alleles of each gene, located at the corresponding site (locus) on **homologous chromosomes**.

allosteric Referring to proteins and cellular processes that are regulated by **allostery**.

allostery Change in the tertiary and/or quaternary structure of a protein induced by binding of a small molecule to a specific regulatory site, causing a change in the protein's activity.

alpha (α) carbon atom (C α) In amino acids, the central carbon atom that is bonded to four different chemical groups (except in glycine) including the **side chain**, or R group. (Figure 2-4)

alpha (α) helix Common protein secondary structure in which the linear sequence of amino acids is folded into a right-handed spiral stabilized by hydrogen bonds between carboxyl and amide groups in the backbone. (Figure 3-4)

alternative splicing Process by which the exons of one pre-mRNA are spliced together in different combinations, generating two or more different mature mRNAs from a single pre-mRNA. (Figure 4-16)

amino acid An organic compound containing at least one amino group and one carboxyl group. In the amino acids that are the monomers for building proteins, an amino group and carboxyl group are linked to a central carbon atom, the α carbon, to which a variable side chain is attached. (Figures 2-4 and 2-14)

aminoacyl-tRNA Activated form of an amino acid, used in protein synthesis, consisting of an amino acid linked via a high-energy ester bond to the 3'-hydroxyl group of a tRNA molecule. (Figure 4-19)

amphipathic Referring to a molecule or structure that has both a hydrophobic and a hydrophilic part.

amphitelic attachment Describes the correct attachment of chromosomes to the mitotic spindle, where sister kinetochores attach to microtubules emanating from opposite poles. (Figure 19-25)

anaerobic Referring to a cell, organism, or metabolic process that functions in the absence of gaseous oxygen (O_2).

anaphase Mitotic stage during which the sister chromatids (or duplicated homologs in meiosis I) separate and move apart (segregate) toward the spindle poles. (Figure 18-36)

anchoring junctions Specialized regions on the cell surface containing cell-adhesion molecules or adhesion receptors; includes *adherens junctions* and *desmosomes*, which mediate cell-cell adhesion, and *hemidesmosomes*, which mediate cell-matrix adhesion. (Figures 20-13 and 20-15)

anaerobic respiration Respiration in which molecules other than oxygen, such as sulfate or nitrate, are used as the final recipient of the electrons transported via the electron-transport chain.

anaphase-promoting complex or cyclosome (APC/C) A ubiquitin ligase that targets securin, mitotic cyclins, and other proteins for proteasomal degradation from the onset of anaphase until entry into the subsequent cell cycle.

aneuploidy Any deviation from the normal diploid number of chromosomes in which extra copies of one or more chromosomes are present or one of the normal copies is missing.

anion A negatively charged ion.

antagonist A molecule, often synthetic, that blocks the biological function of a natural molecule (e.g., hormone).

antibody A protein (immunoglobulin), normally produced in response to an antigen, that interacts with a particular site (epitope) on the same antigen and facilitates its clearance from the body. (Figure 3-19)

anticodon Sequence of three nucleotides in a tRNA that is complementary to a codon in an mRNA. During protein synthesis, base pairing between a codon and anticodon aligns the tRNA carrying the corresponding amino acid for addition to the growing polypeptide chain. (Figure 4-20)

antigen Any material (usually foreign) that elicits an immune response. For B cells, an antigen elicits formation of antibody that specifically binds the same antigen; for T cells, an antigen elicits a proliferative response, followed by production of cytokines or the activation of cytotoxic activity.

antigen-presenting cell (APC) Any cell that can digest an antigen into small peptides and display the peptides in association with class II MHC molecules on the cell surface where they can be recognized by T cells. *Professional APCs* (dendritic cells, macrophages, and B cells) constitutively express class II MHC molecules. (Figures 23-25 and 23-26)

antiport A type of cotransport in which a membrane protein (*antiporter*) transports two different molecules or ions across a cell membrane in opposite directions. See also *symport*. (Figure 11-2, [3C])

apical Referring to the tip (apex) of a cell, an organ, or other body structure. In the case of epithelial cells, the apical surface is exposed to the exterior of the body or to an internal open space (e.g., intestinal lumen, duct). (Figure 20-9)

apoptosis A genetically regulated process, occurring in specific tissues during development and disease, by which a cell destroys itself; marked by the breakdown of most cell components and a series of well-defined morphological changes; also called *programmed cell death*. See also *caspases*. (Figures 21-30, and 21-38)

apoptosome Large, disk-shaped heptamer of mammalian Apaf-1, a protein that assembles in response to apoptosis signals and serves as an activation machine for initiator and effector caspases. (Figure 21-39)

aquaporins A family of membrane transport proteins that allow water and a few other small uncharged molecules, such as glycerol, to cross biomembranes. (Figure 11-8)

archaea Class of prokaryotes that constitutes one of the three distinct evolutionary lineages of modern-day organisms; also called *archaeobacteria* and *archaeans*. In some respects, archaeans are more similar to eukaryotes than to bacteria (eubacteria). (Figure 1-1)

associated constant (K_a) See *equilibrium constant*.

aster Structure composed of microtubules (astral fibers) that radiate outward from a centrosome during mitosis. (Figure 18-37)

astrocytes Star-shaped glial cells in the brain and spinal cord that perform many functions, including support of endothelial cells that form the blood-brain barrier, maintain extracellular ion composition, and provide nutrients to neurons.

asymmetric carbon atom A carbon atom bonded to four different atoms or chemical groups; also called *chiral carbon atom*. The bonds can be arranged in two different ways, producing stereoisomers that are mirror images of each other. (Figure 2-4)

asymmetric cell division Any cell division in which the two daughter cells receive the same genes but otherwise inherit different components (e.g., mRNAs, proteins) from the parental cell. (Figure 21-21a)

ATM/ATR Two related protein kinases that are activated by DNA damage. Once active, they phosphorylate other proteins to initiate the cell's response to DNA damage.

ATP (adenosine 5'-triphosphate) A nucleotide that is the most important molecule for capturing and transferring free energy in cells. Hydrolysis of each of the two **phosphoanhydride bonds** in ATP releases a large amount of free energy that can be used to drive energy-requiring cellular processes. (Figure 2-31)

ATPase One of a large group of enzymes that catalyze hydrolysis of ATP to yield ADP and inorganic phosphate with release of free energy. See also Na^+/K^+ ATPase and **ATP-powered pump**.

ATP-powered pump Any transmembrane protein that has ATPase activity and couples hydrolysis of ATP to the active transport of an ion or small molecule across a biomembrane against its electrochemical gradient; often simply called *pump*. (Figure 11-9)

ATP synthase Multimeric protein complex, bound to inner mitochondrial membranes, thylakoid membranes of chloroplasts, and the bacterial plasma membrane, that catalyzes synthesis of ATP during oxidative phosphorylation and photosynthesis; also called *F₀F₁ complex*. (Figure 12-26a)

ATR See ATM/ATR.

Aurora B kinase Destabilizes faulty microtubule-kinetochore interactions by phosphorylating microtubule-binding components within the kinetochore.

Aurora kinases Serine/threonine kinases that play a crucial role in cell division by controlling chromatid segregation. **Aurora B kinase** destabilizes faulty microtubule-kinetochore interactions by phosphorylating microtubule-binding components within the kinetochore.

autocrine Referring to signaling mechanism in which a cell produces a signaling molecule (e.g., growth factor) and then binds and responds to it.

autophagy Literally, "eating oneself"; the process by which cytosolic proteins and organelles are delivered to the lysosome, degraded, and recycled. Autophagy involves the formation of a double-membrane vesicle called an autophagosome or autophagic vesicle. (Figure 14-35)

autoradiography Technique for visualizing radioactive molecules in a sample (e.g., a tissue section or electrophoretic gel) by exposing a photographic film (emulsion) or two-dimensional electronic detector to the sample. The exposed film is called an *autoradiogram* or *autoradiograph*.

autosome Any chromosome other than a sex chromosome.

axon Long process extending from the cell body of a neuron that is capable of conducting an electric impulse (**action potential**), generated at the junction with the cell body, toward its distal, branching end (the axon terminus). (Figure 22-1)

axonal transport Motor protein-mediated transport of organelles and vesicles along microtubules in axons of nerve cells. *Anterograde* transport occurs from cell body toward axon terminal; *retrograde* transport, from axon terminal toward cell body. (Figures 18-16 and 18-17)

axoneme Bundle of microtubules and associated proteins present in cilia and flagella and responsible for their structure and movement. (Figure 18-30)

bacteria Class of prokaryotes that constitutes one of the three distinct evolutionary lineages of modern-day organisms; also

called *eubacteria*. Phylogenetically distinct from archaea and eukaryotes. (Figure 1-1)

bacteriophage (phage) Any virus that infects bacterial cells. Some phages are widely used as vectors in DNA cloning.

basal See basolateral.

basal body Structure at the base of a cilium or flagellum from which microtubules forming the axoneme assemble; structurally similar to a centriole. (Figure 18-30)

basal lamina (pl. basal laminae) A thin sheet-like network of extracellular-matrix components that underlies most animal epithelia and other organized groups of cells (e.g., muscle), separating them from connective tissue or other cells. (Figures 20-21 and 20-22)

base Any compound, often containing nitrogen, that can accept a proton (H^+) from an acid. Also, commonly used to denote the purines and pyrimidines in DNA and RNA.

base pair Association of two complementary nucleotides in a DNA or RNA molecule stabilized by hydrogen bonding between their base components. Adenine pairs with thymine or uracil ($\text{A} \cdot \text{T}$, $\text{A} \cdot \text{U}$) and guanine pairs with cytosine ($\text{G} \cdot \text{C}$). (Figure 4-3b)

basic helix-loop-helix See helix-loop-helix, basic.

basolateral Referring to the base (basal) and side (lateral) of a polarized cell, organ, or other body structure. In the case of epithelial cells, the basolateral surface abuts adjacent cells and the underlying basal lamina. (Figure 20-9)

B cell A lymphocyte that matures in the bone marrow and expresses antigen-specific receptors (membrane-bound immunoglobulin). After interacting with antigen, a B cell proliferates and differentiates into antibody-secreting plasma cells.

B-cell receptor Complex composed of an antigen-specific membrane-bound immunoglobulin molecule and associated signal-transducing $\text{Ig}\alpha$ and $\text{Ig}\beta$ chains. (Figure 23-16)

benign Referring to a tumor containing cells that closely resemble normal cells. Benign tumors stay in the tissue where they originate but can be harmful due to continued growth. See also malignant.

beta (β)-adrenergic receptors Seven spanning G protein-coupled receptors that bind adrenaline and related molecules, leading to activation of adenylyl cyclase.

beta (β) sheet A flat secondary structure in proteins that is created by hydrogen bonding between the backbone atoms in two different polypeptide chains or segments of a single folded chain. (Figure 3-5)

beta (β) turn A short U-shaped secondary structure in proteins. (Figure 3-6)

bi-oriented Indicates that the kinetochores of sister chromatids have attached to microtubules emanating from opposite spindle poles.

blastocyst Stage of mammalian embryo composed of ≈ 64 cells that have separated into two cell types—trophoblast, which will form extra-embryonic tissues, and the inner cell mass, which gives rise to the embryo proper; stage that implants in the uterine wall and corresponds to the blastula of other animal embryos. (Figure 21-3)

blastopore The first opening that forms during embryogenesis of bilaterally symmetric animals, which later becomes the gut. This opening may become either the mouth or the anus.

buffer A solution of the acid (HA) and base (A^-) form of a compound that undergoes little change in pH when small quantities of strong acid or base are added at pH values near the compound's pK_a .

cadherins A family of dimeric **cell-adhesion molecules** that aggregate in adherens junctions and desmosomes and mediate Ca^{2+} -dependent cell-cell homophilic interactions. (Figure 20-2)

calmodulin A small cytosolic regulatory protein that binds four Ca^{2+} ions. The Ca^{2+} /calmodulin complex binds to many proteins, thereby activating or inhibiting them. (Figure 3-31)

Calvin cycle The major metabolic pathway that fixes CO_2 into carbohydrates during photosynthesis; also called *carbon fixation*. It is indirectly dependent on light but can occur both in the dark and light. (Figure 12-46)

cancer General term denoting any of various malignant tumors, whose cells grow and divide more rapidly than normal, invade surrounding tissue, and sometimes spread (metastasize) to other sites.

capsid The outer proteinaceous coat of a **virus**, formed by multiple copies of one or more protein subunits and enclosing the viral nucleic acid.

CAP site The DNA sequence in bacteria bound by catabolite activator protein, also known as the cyclic AMP regulatory protein. (Figure 7-3)

carbohydrate General term for certain polyhydroxyaldehydes, polyhydroxyketones, or compounds derived from these usually having the formula $(CH_2O)_n$. Primary type of compound used for storing and supplying energy in animal cells. (Figure 2-18)

carbon fixation See **Calvin cycle**.

carcinogen Any chemical or physical agent that can cause cancer when cells or organisms are exposed to it.

caretaker gene Any gene whose encoded protein helps protect the integrity of the genome by participating in the repair of damaged DNA. Loss of function of a caretaker gene leads to increased mutation rates and promotes carcinogenesis.

caspases A class of vertebrate protein-degrading enzymes (proteases) that function in **apoptosis** and work in a cascade with each type activating the next. (Figures 21-33 and 21-38)

catabolism Cellular degradation of complex molecules to simpler ones usually accompanied by the release of energy. *Anabolism* is the reverse process in which energy is used to synthesize complex molecules from simpler ones.

catalyst A substance that increases the rate of a chemical reaction without undergoing a permanent change in its structure. Enzymes are proteins with catalytic activity, and ribozymes are RNAs that can function as catalysts. (Figure 3-20)

cation A positively charged ion.

Cdc25 phosphatases A protein phosphatase that dephosphorylates CDKs on threonine 14 and tyrosine 15, thereby activating CDKs.

CDK-activating kinase (CAK) Phosphorylates CDKs on a threonine residue near the active site. This phosphorylation is essential for CDK activity.

CDK inhibitor (CKI) Binds to cyclin-CDK complex and inhibits its activity.

cDNA (complementary DNA) DNA molecule copied from an mRNA molecule by **reverse transcriptase** and therefore lacking the **introns** present in the DNA of the genome.

cell-adhesion molecules (CAMs) Proteins in the plasma membrane of cells that bind similar proteins on other cells, thereby mediating cell-cell adhesion. Four major classes of CAMs include the **cadherins**, **IgCAMs**, **integrins**, and **selectins**. (Figures 20-1 and 20-2)

cell-adhesion proteins See **cell adhesion molecules (CAMs)**.

cell cycle Ordered sequence of events in which a eukaryotic cell duplicates its chromosomes and divides into two. The cell cycle normally consists of four phases: G_1 before DNA synthesis occurs; S when DNA replication occurs; G_2 after DNA synthesis; and M when **cell division** occurs, yielding two daughter cells. Under certain conditions, cells exit the cell cycle during G_1 and remain in the G_0 state as nondividing cells. (Figures 1-16 and 19-1)

cell division Separation of a cell into two daughter cells. In higher eukaryotes, it involves division of the nucleus (**mitosis**) and of the cytoplasm (**cytokinesis**); mitosis often is used to refer to both nuclear and cytoplasmic division.

cell junctions Specialized regions on the cell surface through which cells are joined to each other or to the extracellular matrix. (Figure 20-10; Table 20-2)

cell line A population of cultured cells, of plant or animal origin, that has undergone a genetic change allowing the cells to grow indefinitely. (Figure 9-1b)

cell polarity The ability of cells to organize their internal structure, resulting in changes of cell shape and generating regions of the plasma membrane with different protein and lipid compositions.

cell strain A population of cultured cells, of plant or animal origin, that has a finite life span and eventually dies, commonly after 25–50 generations. (Figure 9-1a)

cellular respiration See **respiration**.

cellulose A structural polysaccharide made of glucose units linked together by $\beta(1 \rightarrow 4)$ **glycosidic bonds**. It forms long microfibrils, which are the major component of the **cell wall** in plants.

cell wall A specialized, rigid extracellular matrix that lies next to the plasma membrane, protecting a cell and maintaining its shape; prominent in most fungi, plants, and prokaryotes but absent in most multicellular animals. (Figure 20-40)

centriole Either of two cylindrical structures within the **centrosome** of animal cells and containing nine sets of triplet microtubules; structurally similar to a **basal body**. (Figure 18-6)

centromere DNA sequence required for proper **segregation** of chromosomes during mitosis and meiosis; the region of mitotic chromosomes where the **kinetochore** forms and that appears constricted. (Figure 6-39)

centrosome (cell center) Structure located near the nucleus of animal cells that is the primary **microtubule-organizing center (MTOC)**; it contains a pair of **centrioles** embedded in a protein matrix and duplicates before mitosis, with each centrosome becoming a spindle pole. (Figures 18-6 and 18-35)

centrosome disjunction Describes the process of centrosome segregation during prophase.

channels Membrane proteins that transport water, ions, or small hydrophilic molecules across membranes down their concentration or electric potential gradients.

chaperone Collective term for two types of proteins—**molecular chaperones** and **chaperonins**—that prevent misfolding of a target protein or actively facilitate proper folding of an incompletely folded target protein, respectively. (Figures 3-16 and 3-17)

chaperonin See **chaperone**.

checkpoint Any of several points in the eukaryotic cell cycle at which progression of a cell to the next stage can be halted until conditions are suitable.

checkpoint pathway Surveillance mechanism that prevents initiation of each step in cell division until earlier steps on which it depends have been completed and mistakes that occurred during the process have been corrected.

chemical equilibrium The state of a chemical reaction in which the concentration of all products and reactants is constant because the rates of the forward and reverse reactions are equal.

chemical potential energy The energy stored in the bonds connecting atoms in molecules.

chemiosmosis Process whereby an electrochemical proton gradient (pH plus electric potential) across a membrane is used to drive an energy-requiring process such as ATP synthesis; also called *chemiosmotic coupling*. See **proton-motive force**. (Figure 12-2)

chemokine Any of numerous small, secreted proteins that function as chemotactic cues for leukocytes.

chemotaxis Movement of a cell or organism toward or away from certain chemicals.

chlorophylls A group of light-absorbing porphyrin pigments that are critical in **photosynthesis**. (Figure 12-33)

chloroplast A specialized organelle in plant cells that is surrounded by a double membrane and contains internal chlorophyll-containing membranes (**thylakoids**) where the light-absorbing reactions of photosynthesis occur. (Figure 12-31)

cholesterol A lipid containing the four-ring steroid structure with a hydroxyl group on one ring; a component of many eukaryotic membranes and the precursor of steroid hormones, bile acids, and vitamin D. (Figure 10-8c)

chromatid One copy of a replicated chromosome, formed during the S phase of the cell cycle, that is joined to the other copy; also called **sister chromatid**. During mitosis, the two chromatids separate, each becoming a chromosome of one of the two daughter cells. (Figure 6-39)

chromatin Complex of DNA, histones, and nonhistone proteins from which eukaryotic chromosomes are formed. Condensation of chromatin during mitosis yields the visible **metaphase chromosomes**. (Figures 6-28 and 6-30)

chromatography, liquid Group of biochemical techniques for separating mixtures of molecules (e.g., different proteins) based on their mass (*gel filtration chromatography*), charge (*ion exchange chromatography*), or ability to bind specifically to other molecules (*affinity chromatography*). (Figure 3-38)

chromosome In eukaryotes, the structural unit of the genetic material consisting of a single, linear double-stranded DNA molecule and associated proteins. In most prokaryotes, a single, circular double-stranded DNA molecule constitutes the bulk of the genetic material. See also **chromatin** and **karyotype**.

cilium (pl. **cilia**) Short, membrane-enclosed structure extending from the surface of eukaryotic cells and containing a core bundle of **microtubules**. Cilia usually occur in groups and beat rhythmically to move a cell (e.g., single-celled organism) or to move small particles or fluid along a surface (e.g., trachea cells). See also **axoneme** and **flagellum**.

cisterna (pl. **cisternae**) Flattened membrane-bounded compartment, as found in the Golgi complex and endoplasmic reticulum.

citric acid cycle A set of nine coupled reactions occurring in the matrix of the **mitochondrion** in which acetyl groups are oxidized, generating CO₂ and reduced intermediates used to produce ATP; also called *Krebs cycle* and *tricarboxylic acid (TCA) cycle*. (Figure 12-10)

clathrin A fibrous protein that with the aid of assembly proteins polymerizes into a lattice-like network at specific regions on the cytosolic side of a membrane, thereby forming a clathrin-coated pit that buds off to form a vesicle. (Figure 14-18; Table 14-1)

cleavage In embryogenesis, the series of rapid cell divisions that occurs following fertilization and with little cell growth, producing progressively smaller cells; culminates in formation of the blastocyst in mammals or blastula in other animals. Also used as a synonym for the hydrolysis of molecules. (Figure 21-3)

cleavage furrow Indentation in the plasma membrane that represents the initial steps in cytokinesis.

cleavage/polyadenylation complex Large, multiprotein complex that catalyzes the cleavage of **pre-mRNA** at a 3' poly(A) site and the initial addition of adenylate (A) residues to form the poly(A) tail. (Figure 8-15)

clone (1) A population of genetically identical cells, viruses, or organisms descended from a common ancestor. (2) Multiple identical copies of a gene or DNA fragment generated and maintained via **DNA cloning**.

codon Sequence of three nucleotides in DNA or mRNA that specifies a particular amino acid during protein synthesis; also called *triplet*. Of the 64 possible codons, three are stop codons, which do not specify amino acids and cause termination of synthesis. (Table 4-1)

cohesin complex Protein complex that establishes cohesion between **sister chromatids**.

coiled coil A protein **structural motif** marked by amphipathic α helical regions that can self-associate to form stable, rodlike structures in proteins; commonly found in fibrous proteins and certain transcription factors. (Figure 3-9a)

collagen A triple-helical glycoprotein rich in glycine and proline that is a major component of the **extracellular matrix** and connective tissues. The numerous subtypes differ in their tissue distribution and the extracellular components and cell-surface proteins with which they associate. (Figure 20-24; Table 20-4)

complement A group of constitutive serum proteins that bind directly to microbial or fungal surfaces, thereby activating a proteolytic cascade that culminates in formation of the cytolytic **membrane attack complex**. (Figure 23-4).

complementary (1) Referring to two nucleic acid sequences or strands that can form perfect **base pairs** with each other. (2) Describing regions on two interacting molecules (e.g., an enzyme and its substrate) that fit together in a lock-and-key fashion.

complementary DNA (cDNA) See **cDNA**.

complementation See **genetic complementation** and **functional complementation**.

concentration gradient In cell biology, a difference in the concentration of a substance in different regions of a cell or embryo or on different sides of a cellular membrane.

condensin complex Protein complex related to cohesins that compacts chromosomes and is necessary for their segregation during mitosis.

conformation The precise shape of a protein or other macromolecule in three dimensions resulting from the spatial location of the atoms in the molecule. (Figure 3-8)

connexins A family of transmembrane proteins that form **gap junctions** in vertebrates. (Figure 20-20)

constitutive Referring to the continuous production or activity of a cellular molecule or the continuous operation of a cellular process (e.g., constitutive secretion) that is not regulated by internal or external signals.

contractile bundles Bundles of **actin** and **myosin** in nonmuscle cells that function in cell adhesion (e.g., *stress fibers*) or cell movement (*contractile ring* in dividing cells).

contractile ring Composed of actin and myosin; located beneath the plasma membrane. During cytokinesis, its contraction pulls the membrane inward, eventually closing the connection between the two daughter cells.

contractile vacuole A vesicle found in many protozoans that takes up water from the cytosol and periodically discharges its contents through fusion with the plasma membrane.

coordinately regulated Genes whose expression are induced and repressed at the same time, as for the genes in a single bacterial operon. (Figure 4-13)

co-oriented Indicates that sister kinetochores attach to microtubules emanating from the *same* spindle pole rather than from opposite spindle poles.

COPI A class of proteins that coat transport vesicles in the **secretory pathway**. COPI-coated vesicles move proteins from the Golgi to the endoplasmic reticulum and from later to earlier Golgi cisternae. (Table 14-1)

COPII A class of proteins that coat transport vesicles in the **secretory pathway**. COPII-coated vesicles move proteins from the endoplasmic reticulum to the Golgi. (Table 14-1)

cotranslational translocation Simultaneous transport of a secretory protein into the endoplasmic reticulum as the nascent protein is still bound to the ribosome and being elongated. (Figure 13-6)

cotransport Protein-mediated movement of an ion or small molecule across a membrane against a concentration gradient driven by coupling to movement of a second molecule down its concentration gradient in the same (**symport**) or opposite (**antiport**) direction. (Figure 11-2, [3B, C]; Table 11-1)

covalent bond Stable chemical force that holds the atoms in molecules together by sharing of one or more pairs of electrons. See also **noncovalent interaction**. (Figures 2-2 and 2-6)

CpG islands Regions in vertebrate DNA ~100 to ~1000 bp that have an unusually high occurrence of the sequence CG. Many CpG islands function as promoters for transcription initiation, usually in both directions.

critical cell size Defines the size that a cell must reach before it can enter the cell cycle.

cross-exon recognition complex Large assembly including RNA-binding SR proteins and other components that helps delineate exons in the **pre-mRNAs** of higher eukaryotes and ensure correct **RNA splicing**. (Figure 8-13)

crossing over Exchange of genetic material between maternal and paternal **chromatids** during **meiosis** to produce recombined chromosomes. See also **recombination**. (Figure 5-10)

cyclic AMP (cAMP) A **second messenger**, produced in response to hormonal stimulation of certain G protein-coupled receptors, that activates **protein kinase A**. (Figure 15-8; Table 15-2)

cyclic GMP (cGMP) A **second messenger** that opens cation channels in rod cells and activates protein kinase G in vascular smooth muscle and other cells. (Figures 15-8, 15-23, and 15-37)

cyclin Any of several related proteins whose concentrations rise and fall during the course of the eukaryotic cell cycle. Cyclins form complexes with **cyclin-dependent kinases**, thereby activating and determining the substrate specificity of these enzymes.

cyclin-dependent kinase (CDK) A protein kinase that is catalytically active only when bound to a cyclin. Various cyclin-CDK complexes trigger progression through different stages of the eukaryotic cell cycle by phosphorylating specific target proteins. (Table 19-1)

cytochromes A group of colored, heme-containing proteins, some of which function as **electron carriers** during cellular respiration and photosynthesis. (Figure 12-14a)

cytokine Any of numerous small, secreted proteins (e.g., erythropoietin, G-CSF, interferons, interleukins) that bind to cell-surface receptors on blood and immune-system cells to trigger their differentiation or proliferation.

cytokine receptor Member of major class of cell-surface signaling receptors, including those for erythropoietin, growth hormone, interleukins, and interferons. Ligand binding leads to activation of cytosolic JAK kinases associated with the receptor, thereby initiating intracellular signaling pathways. (Figures 16-2 and 16-13)

cytokinesis The division of the cytoplasm following **mitosis** to generate two daughter cells, each with a nucleus and cytoplasmic organelles. (Figure 17-36)

cytoplasm Viscous contents of a cell that are contained within the plasma membrane but, in eukaryotic cells, outside the nucleus.

cytoskeleton Network of fibrous elements, consisting primarily of **microtubules**, **microfilaments**, and **intermediate filaments**, found in the cytoplasm of eukaryotic cells. The cytoskeleton provides organization and structural support for the cell and permits directed movement of organelles, chromosomes, and the cell itself. (Figures 17-1, 17-2, and 18-1)

cytoskeletal proteins See cytoskeleton.

cytosol Unstructured aqueous phase of the cytoplasm excluding organelles, membranes, and insoluble cytoskeletal components.

cytosolic face The face of a cell membrane directed toward the cytosol. (Figure 10-5)

DAG See diacylglycerol.

dalton Unit of molecular mass approximately equal to the mass of a hydrogen atom (1.66×10^{-24} g).

denaturation Drastic alteration in the **conformation** of a protein or nucleic acid due to disruption of various noncovalent interactions caused by heating or exposure to certain chemicals; usually results in loss of biological function.

dendrite Process extending from the cell body of a neuron that is relatively short and typically branched and receives signals from **axons** of other neurons. (Figure 22-1)

dendritic cells Phagocytic professional **antigen-presenting cells** that reside in various tissues and can detect broad patterns of pathogen markers via their **Toll-like receptors**. After internalizing antigen at a site of tissue injury or infection, they migrate to lymph nodes and initiate activation of **T cells**. (Figure 23-6)

deoxyribonucleic acid See DNA.

depolarization Decrease in the cytosolic-face negative electric potential that normally exists across the plasma membrane of a cell at rest, resulting in a less inside-negative or an inside-positive **membrane potential**.

destruction box Recognition motif in APC/C substrates.

determinant In the context of antibody recognition of an antigen, a region on a protein to which the antibody binds. In this context, it is synonymous with **epitope**.

deuterosomes A group of bilaterally symmetric animals whose anus develops close to the blastopore and has a dorsal nerve cord. This group includes all chordates (fish, amphibians, reptiles, birds, and mammals) and echinoderms (sea stars, sea urchins).

diacylglycerol (DAG) Membrane-bound **second messenger** that can be produced by cleavage of **phosphoinositides** in response to stimulation of certain cell-surface receptors. (Figures 15-8 and 15-35)

diploid Referring to an organism or cell having two full sets of **homologous chromosomes** and hence two copies (**alleles**) of each gene or genetic locus. Somatic cells contain the diploid number of chromosomes ($2n$) characteristic of a species. See also **haploid**.

dipole A positive charge separated in space from an equal but opposite negative charge.

dipole moment A quantitative measure of the extent of charge separation, or strength, of a dipole, which for a chemical bond is the product of the partial charge on each atom and the distance between the two atoms.

disaccharide A small carbohydrate (sugar) composed of two monosaccharides covalently joined by a **glycosidic bond**. (Figure 2-19)

dissociation constant (K_d) See **equilibrium constant**.

disulfide bond ($-S-S-$) A common covalent linkage between the sulfur atoms on two cysteine residues in different polypeptides or in different parts of the same polypeptide.

diversity The entire set of antigen-specific receptors encoded by an immune system.

DNA (deoxyribonucleic acid) Long linear polymer, composed of four kinds of deoxyribose **nucleotides**, that is the carrier of genetic information. See also **double helix**, DNA. (Figure 4-3)

DNA-binding domain The domain of a transcription factor that binds specific, closely related DNA sequences.

DNA cloning Recombinant DNA technique in which specific cDNAs or fragments of genomic DNA are inserted into a cloning **vector**, which then is incorporated into cultured host cells and maintained during growth of the host cells; also called **gene cloning**. (Figure 5-14)

DNA damage response system Pathway that senses DNA damage and induces cell cycle arrest and DNA repair pathways.

DNA library Collection of cloned DNA molecules consisting of fragments of the entire genome (**genomic library**) or of DNA copies of all the mRNAs produced by a cell type (**cDNA library**) inserted into a suitable cloning **vector**.

DNA ligase An enzyme that links together the 3' end of one DNA fragment with the 5' end of another, forming a continuous strand.

DNA microarray An ordered set of thousands of different nucleotide sequences arrayed on a microscope slide or other solid surface; can be used to determine patterns of gene expression in different cell types or in a particular cell type at different developmental stages or under different conditions. (Figures 5-29 and 5-30)

DNA polymerase An enzyme that copies one strand of DNA (the template strand) to make the complementary strand, forming a new double-stranded DNA molecule. All DNA polymerases add deoxyribonucleotides one at a time in the $5' \rightarrow 3'$ direction to the 3' end of a short preexisting primer strand of DNA or RNA.

DNA recombination The process by which two DNA molecules with similar sequences are subject to double-stranded breaks and then rejoined to generate two recombinant DNA molecules with sequences comprised of portions of each parent. (Figures 4-42 and 4-43)

dominant In genetics, referring to that allele of a gene expressed in the **phenotype** of a heterozygote; the nonexpressed allele is **recessive**; also refers to the phenotype associated with a dominant allele. Mutations that produce dominant alleles generally result in a gain of function. (Figure 5-2)

dominant-negative In genetics, an allele that acts in a **dominant** manner but produces an effect similar to a loss of function; generally is an allele encoding a mutant protein that blocks the function of the normal protein by binding either to it or to a protein **upstream** or **downstream** of it in a pathway.

double helix, DNA The most common three-dimensional structure for cellular DNA in which the two polynucleotide strands are antiparallel and wound around each other with complementary bases hydrogen-bonded. (Figure 4-3)

double-strand break Form of DNA damage where both phosphate-sugar backbones of the DNA are severed.

downstream (1) For a gene, the direction RNA polymerase moves during transcription, which is toward the end of the template DNA strand with a 5'-hydroxyl group. Nucleotides downstream from the +1 position (the first transcribed nucleotide) are designated +2, +3, etc. (2) Events that occur later in a cascade of steps (e.g., signaling pathway). See also **upstream**.

dyncins A class of **motor proteins** that use the energy released by ATP hydrolysis to move toward the (–) end of **microtubules**. Dyneins can transport vesicles and organelles, are responsible for the movement of cilia and flagella, and play a role in chromosome movement during mitosis. (Figures 18-23 and 18-24)

ectoderm Outermost of the three primary cell layers of the animal embryo; gives rise to epidermal tissues, the nervous system, and external sense organs. See also **endoderm** and **mesoderm**.

effector Ultimate component of a signal transduction pathway that elicits a response to the transmitted signal.

endoderm Innermost of the three primary cell layers of the animal embryo; gives rise to the gut and most of the respiratory tract. See **ectoderm** and **mesoderm**.

EF hand A type of helix-loop-helix **structural motif** that occurs in many Ca^{2+} -binding proteins such as **calmodulin**. (Figure 3-9b)

efferent neurons Nerves that transmit signals from the central nervous system to peripheral tissues such as muscles and endocrine cells.

electric potential The energy associated with the separation of positive and negative charges. An electric potential is maintained across the plasma membrane of nearly all cells.

electrochemical gradient The driving force that determines the energetically favorable direction of transport of an ion (or charged molecule) across a membrane. It represents the combined influence of the ion's **concentration gradient** across the membrane and the **membrane potential**.

electron carrier Any molecule or atom that accepts electrons from donor molecules and transfers them to acceptor molecules in coupled **oxidation** and **reduction** reactions. (Table 12-2)

electron transport Flow of electrons via a series of electron carriers from reduced electron donors (e.g., NADH) to O_2 in the inner mitochondrial membrane, or from H_2O to NADP^+ in the thylakoid membrane of plant chloroplasts. (Figures 12-19 and 12-32)

electron transport chain Set of four large multiprotein complexes in the inner mitochondrial membrane plus diffusible cytochrome *c* and coenzyme Q through which electrons flow from reduced electron donors (e.g., NADH) to O_2 . Each member of the chain contains one or more bound **electron carriers**. (Figure 12-16)

electrophoresis Any of several techniques for separating macromolecules based on their migration in a gel or other medium subjected to a strong electric field. (Figure 3-36)

elongation, transcription Addition of nucleotides to a growing polynucleotide chain, as templated by a complementary DNA coding strand. (Figure 4-11)

elongation factor (EF) One of a group of nonribosomal proteins required for continued **translation** of mRNA (protein synthesis) following initiation. (Figure 4-25)

embryonic stem (ES) cells A line of cultured cells derived from very early embryos that can differentiate into a wide range of cell types either in vitro or after reinsertion into a host embryo. (Figure 21-5)

endergonic Referring to reactions and processes that have a positive ΔG and thus require an input of **free energy** in order to proceed; opposite of **exergonic**.

endocrine Referring to signaling mechanism in which target cells bind and respond to a **hormone** released into the blood by distant specialized secretory cells usually present in a gland (e.g., pituitary or thyroid gland).

endocytic pathway Cellular pathway involving **receptor-mediated endocytosis** that internalizes extracellular materials too large to be imported by membrane transport proteins and to remove receptor proteins from the cell surface as a way to down-regulate their activity. (Figure 14-29)

endocytosis General term for uptake of extracellular material by invagination of the plasma membrane; includes **receptor-mediated endocytosis**, **phagocytosis**, and **pinocytosis**.

endoplasmic reticulum (ER) Network of interconnected membranous structures within the cytoplasm of eukaryotic cells contiguous with the outer nuclear envelope. The *rough ER*, which is associated with **ribosomes**, functions in the synthesis and processing of secreted and membrane proteins; the *smooth ER*, which lacks ribosomes, functions in lipid synthesis. (Figure 9-32)

endosome One of two types of membrane-bounded compartments: *early endosomes* (or endocytic vesicles), which bud off from the plasma membrane during receptor-mediated endocytosis, and *late endosomes*, which have an acidic internal pH and function in sorting of proteins to **lysosomes**. (Figures 14-1 and 14-29)

endosymbiont Bacterium that resides inside a eukaryotic cell in a mutually beneficial partnership. According to the endosymbiont hypothesis, both mitochondria and chloroplasts evolved from endosymbionts. (Figure 6-20)

endothelium The thin layer of cells that lines the interior surface of blood and lymphatic vessels.

endothermic Referring to reactions and processes that have a positive change in **enthalpy**, ΔH , and thus must absorb heat in order to proceed; opposite of **exothermic**.

energy charge A measure of the fraction of total adenosine phosphates that have "high-energy" phosphoanhydride bonds, which is equal to $([\text{ATP}] + 0.5 [\text{ADP}]) / ([\text{ATP}] + [\text{ADP}] + [\text{AMP}])$.

enhancer A regulatory sequence in eukaryotic DNA that may be located at a great distance from the gene it controls or even within the coding sequence. Binding of specific proteins to an enhancer modulates the rate of transcription of the associated gene. (Figure 7-22)

enhancesome Large nucleoprotein complex that assembles from transcription factors (activators and repressors) as they bind cooperatively to their binding sites in an **enhancer** with the assistance of DNA-bending proteins. (Figure 7-33)

enthalpy (H) Heat; in a chemical reaction, the enthalpy of the reactants or products is equal to their total bond energies.

entropy (S) A measure of the degree of disorder or randomness in a system; the higher the entropy, the greater the disorder.

envelope See nuclear envelope or viral envelope.

enzyme A protein that catalyzes a particular chemical reaction involving a specific substrate or small number of related substrates.

epidermal growth factor (EGF) One of a family of secreted signaling proteins (the *EGF family*) that is used in the development of most tissues in most or all animals. EGF signals are bound by receptor tyrosine kinases. Mutations in EGF signal transduction components are implicated in human cancer, including brain cancer. See HER family.

epigenetic Referring to a process that affects the expression of specific genes and is inherited by daughter cells but does not involve a change in DNA sequence.

epinephrine A catecholamine secreted by the adrenal gland and some neurons in response to stress; also called *adrenaline*. It functions as both a hormone and neurotransmitter, mediating "fight or flight" responses (e.g., increased blood glucose levels and heart rate).

epithelium (pl. *epithelia*) Sheet-like covering, composed of one or more layers of tightly adhering cells, on external and internal body surfaces. (Figure 20-9)

epithelial-to-mesenchymal transition (EMT) Describes a developmental program during which epithelial cells acquire the characteristics of mesenchymal cells. Cells lose adhesive properties and acquire motility.

epitope The part of an antigen molecule that binds to an antigen-specific receptor on B or T cells or to antibody. Large protein antigens usually possess multiple epitopes that bind to antibodies of different specificity.

equilibrium constant (K_{eq}) Ratio of forward and reverse rate constants for a reaction. For a binding reaction, $A + B \rightleftharpoons AB$, the association constant (K_a) equals K , and the dissociation constant (K_d) equals $1/K$.

erythropoietin (Epo) A cytokine that triggers production of red blood cells by inducing the proliferation and differentiation of erythroid progenitor cells in the bone marrow. (Figures 16-8 and 21-23)

E2F transcription factor complex Transcription factor that promotes the transcription of G_1/S phase cyclins and many other genes whose function is required for S phase.

euchromatin Less condensed portions of **chromatin** present in interphase chromosomes; includes most transcriptionally active regions. See also **heterochromatin**. (Figure 6-33a)

eukaryotes Class of organisms, composed of one or more cells containing a membrane-enclosed nucleus and organelles, that constitutes one of the three distinct evolutionary lineages of modern-day organisms; also called *eukarya*. Includes all organisms except viruses and prokaryotes. (Figure 1-1)

eukaryotic translation initiation factors (eIFs) Proteins required to initiate protein synthesis in eukaryotic cells. (Figure 4-24)

excision-repair system, DNA One of several mechanisms for repairing DNA damage due to spontaneous depurination or deamination or exposure to **carcinogens**. These repair systems normally operate with a high degree of fidelity and their loss is associated with increased risk for certain cancers.

excitatory synapse A synapse in which the neurotransmitter induces a depolarization of the postsynaptic cell, favoring generation of an action potential.

exergonic Referring to reactions and processes that have a negative ΔG and thus release **free energy** as they proceed; opposite of **endergonic**.

exocytosis Release of intracellular molecules (e.g., hormones, matrix proteins) contained within a membrane-bounded vesicle by fusion of the vesicle with the plasma membrane of a cell.

exon Segment of a eukaryotic gene (or of its **primary transcript**) that reaches the cytoplasm as part of a mature mRNA, rRNA, or tRNA molecule. See also **intron**.

exon shuffling Evolutionary process for creating new genes (i.e., new combinations of exons) from preexisting ones by recombination between introns of two separate genes or by transposition of mobile DNA elements. (Figures 6-18 and 6-19)

exoplasmic face The face of a cell membrane directed away from the cytosol. (Figure 10-5)

exosome Large exonuclease-containing complex that degrades spliced-out introns and improperly processed pre-mRNAs in the nucleus or mRNAs with shortened poly(A) tails in the cytoplasm. (Figure 8-1)

exothermic Referring to reactions and processes that have a negative change in **enthalpy**, ΔH , and thus release heat as they proceed; opposite of **endothermic**.

expression vector A modified **plasmid** or virus that carries a gene or cDNA into a suitable host cell and there directs synthesis of the encoded protein; used to screen a DNA library for a gene of interest or to produce large amounts of a protein from its cloned gene (Figures 5-31 and 5-32)

extracellular matrix (ECM) A complex interdigitating meshwork of proteins and polysaccharides secreted by cells into the spaces between them. It provides structural support in tissues and can affect the development and biochemical functions of cells. (Table 20-1)

F_0F_1 complex See **ATP synthase**.

facilitated transport Protein-aided transport of an ion or small molecule across a cell membrane down its concentration gradient at a rate greater than that obtained by **simple diffusion**; also called *facilitated diffusion*. (Table 11-1)

FAD (flavin adenine dinucleotide) A small organic molecule that functions as an electron carrier by accepting two electrons from a donor molecule and two H^+ from the solution. (Figure 2-33b) **fatty acid** Any long hydrocarbon chain that has a carboxyl group at one end; a major source of energy during metabolism and a precursor for synthesis of phospholipids, triglycerides, and cholesterol esters. (Figure 2-21; Table 2-4)

fermentation The conversion of some of the energy in organic molecule nutrients such as glucose into ATP via their oxidation into organic molecule "waste" products such as lactic acid or ethanol, typically involving the simultaneous cyclical reduction and oxidation of $NAD^+/NADH$.

FG-nucleoporins Proteins on the inner surface of the nuclear pore complex with a globular domain that forms part of the pore structure and a random coil domain of hydrophilic amino acids punctuated by short repeats rich in phenylalanine and glycine. (Figure 8-20)

fibroblast A common type of connective tissue cell that secretes collagen and other components of the **extracellular matrix**; migrates and proliferates during wound healing and in tissue culture.

fibronectin An abundant **multi-adhesive matrix protein** that occurs in numerous isoforms, generated by alternative splicing, in various cell types. Binds many other components of the extracellular matrix and to integrin adhesion receptors. (Figure 20-32)

FISH See **fluorescence in situ hybridization**.

flagellum (pl. **flagella**) Long locomotory structure (usually one per cell) extending from the surface of some eukaryotic cells (e.g., **sperm**), whose whiplike bending propels the cell through a fluid medium. Bacterial flagella are smaller and much simpler structures. See also **axoneme** and **cilium**. (Figure 18-31)

flavin adenine dinucleotide See **FAD**.

flippase Protein that facilitates the movement of membrane lipids from one leaflet to the other leaflet of a phospholipid bilayer. (Figure 11-15)

fluorescence in situ hybridization (FISH) Any of several related techniques for detecting specific DNA or RNA sequences in cells and tissues by treating samples with fluorescent **probes** that hybridize to the sequence of interest and observing the samples by fluorescence microscopy.

fluorescent staining General technique for visualizing cellular components by treating cells or tissues with a fluorescent dye-labeled agent (e.g., antibody) that binds specifically to a component of interest and observing the sample by fluorescence microscopy.

free energy (G) A measure of the potential energy of a system, which is a function of the **enthalpy (H)** and **entropy (S)**.

functional complementation Procedure for screening a DNA library to identify the wild-type gene that restores the function of a defective gene in a particular mutant. (Figure 5-18)

G₀, G₁, G₂ phase See **cell cycle**.

G₁ CDKs Cyclin-CDK complexes that promote entry into the cell cycle.

G₁/S phase CDKs Cyclin-CDK complexes that promote entry into the cell cycle together with G₁ CDKs.

gamete Specialized **haploid** cell (in animals either a sperm or an egg) produced by **meiosis** of precursor **germ cells**; in sexual reproduction, union of a sperm and an egg initiates the development of a new individual.

gap junction Protein-lined channel connecting the cytoplasm of adjacent animal cells that allows passage of ions and small molecules between the cells. See also **plasmodesmata**. (Figure 20-20)

gene Physical and functional unit of heredity, which carries information from one generation to the next. In molecular terms, it is the entire DNA sequence—including **exons**, **introns**, and **transcription-control regions**—necessary for production of a functional polypeptide or RNA. See also **transcription unit**.

gene conversion A type of DNA recombination in which one DNA sequence is converted to the sequence of a second homologous DNA sequence in the same cell.

gene control All of the mechanisms involved in regulating **gene expression**. Most common is regulation of transcription, although mechanisms influencing the processing, stabilization, and translation of mRNAs help control expression of some genes.

gene expression Overall process by which the information encoded in a gene is converted into an observable **phenotype** (most commonly production of a protein).

gene family Set of genes that arose by duplication of a common ancestral gene and subsequent divergence due to small changes in the nucleotide sequence. (Figure 6-26)

gene knockout See **knockout, gene**.

genetic code The set of rules whereby nucleotide triplets (**codons**) in DNA or RNA specify amino acids in proteins. (Table 4-1)

genetic complementation Restoration of a wild-type function in diploid heterozygous cells generated from haploid cells, each of which carries a mutation in a different gene whose encoded protein is required for the same biochemical pathway. Complementation analysis can determine if recessive mutations in two mutants with the same mutant phenotype are in the same or different genes. (Figure 5-7)

genome Total genetic information carried by a cell or organism.

genomics Comparative analyses of the complete genomic sequences from different organisms and determination of global patterns of gene expression; used to assess evolutionary relations among species and to predict the number and general types of RNAs produced by an organism.

genotype Entire genetic constitution of an individual cell or organism, usually with emphasis on the particular alleles at one or more specific loci.

germ cell In sexually reproducing organisms, any cell that can potentially contribute to the formation of offspring including gametes and their immature precursors; also called **germ-line cell**. See also **somatic cell**.

glia Supporting cells of nervous tissue that, unlike neurons, do not conduct electrical impulses; also called **glial cells**. Of the four types, **Schwann cells** and **oligodendrocytes** produce **myelin sheaths**, **astrocytes** function in **synapse** formation, and **microglia** make **trophic factors** and serve in immune responses. (Figure 22-14)

glucagon A peptide hormone produced in the cells of pancreatic islets that triggers the conversion of glycogen to glucose by the liver; acts with **insulin** to control blood glucose levels.

GLUT proteins A family of transmembrane proteins, containing 12 membrane-spanning α helices, that transport glucose (and a few other sugars) across cell membranes down its concentration gradient. (Figure 11-5)

glycogen A very long, branched polysaccharide, composed exclusively of glucose units, that is the primary storage carbohydrate in animals; found primarily in liver and muscle cells.

glycolipid Any lipid to which a short carbohydrate chain is covalently linked; commonly found in the plasma membrane.

glycolysis Metabolic pathway in which sugars are degraded anaerobically to lactate or pyruvate in the cytosol with the production of ATP. (Figure 12-3)

glycoprotein Any protein to which one or more oligosaccharide chains are covalently linked. Most secreted proteins and many membrane proteins are glycoproteins.

glycosaminoglycan (GAG) A long, linear, highly charged polymer of a repeating disaccharides in which many residues often are sulfated. GAGs are major components of the extracellular matrix, usually as components of **proteoglycans**. (Figure 20-28)

glycosidic bond The covalent linkage between two monosaccharide residues formed when a carbon atom in one sugar reacts with a hydroxyl group on a second sugar with the net release of a water molecule (dehydration). (Figure 2-13)

G protein-coupled receptor (GPCR) Member of a large class of cell-surface signaling receptors, including those for epinephrine, glucagon, and yeast mating factors. All GPCRs contain seven transmembrane α helices. Ligand binding leads to activation of a coupled trimeric G protein, thereby initiating intracellular signaling pathways. (Figures 15-15 and 15-17)

Golgi complex Stacks of flattened, interconnected membrane-bounded compartments (cisternae) in eukaryotic cells that function in processing and sorting of proteins and lipids destined for other cellular compartments or for secretion; also called *Golgi apparatus*. (Figure 9-28)

growth factor An extracellular polypeptide molecule that binds to a cell-surface receptor, triggering an intracellular signaling pathway generally leading to cell proliferation.

GTPase superfamily Group of intracellular switch proteins that cycle between an inactive state with bound GDP and an active state with bound GTP. Includes the $G\alpha$ subunit of trimeric (large) **G proteins**, monomeric (small) **G proteins** (e.g., Ras, Rab, Ran, and Rac), and certain **elongation factors** used in protein synthesis. (Figure 3-32)

haploid Referring to an organism or cell having only one member of each pair of **homologous chromosomes** and hence only one copy (allele) of each gene or genetic locus. Gametes and bacterial cells are haploid. See also **diploid**.

Hedgehog (Hh) A family of secreted signaling proteins that are important regulators of the development of most tissues and organs in diverse animal species. Mutations in Hh signal transduction components are implicated in human cancer and birth defects. The receptor is the Patched transmembrane protein. (Figures 16-31, 16-32 and 16-33)

helicase (1) Any enzyme that moves along a DNA duplex using the energy released by ATP hydrolysis to separate (unwind) the two strands; required for DNA replication. (2) Activity of certain initiation factors that can unwind the secondary structures in mRNA during initiation of translation.

helix-loop-helix, basic (bHLH) A conserved DNA-binding structural motif, consisting of two α helices connected by a short loop, that is found in many dimeric eukaryotic transcription factors. (Figure 7-29d)

helix-turn-helix A structural motif in which two alpha helices are connected by a short stretch of connecting residues, sometimes also called a "loop." Helix-turn-helix/helix-loop-helix structural motifs can perform various functions, including binding calcium and binding DNA.

HER family Group of receptors, belonging to the **receptor tyrosine kinase (RTK)** class, that bind to members of the epidermal growth factor (EGF) family of signaling molecules in humans.

Overexpression of HER2 protein is associated with some breast cancers. (Figure 16-7)

heterochromatin Regions of **chromatin** that remain highly condensed and transcriptionally inactive during interphase. (Figure 6-33a)

heterozygous Referring to a diploid cell or organism having two different alleles of a particular gene.

hexose A six-carbon monosaccharide.

high-energy bond Covalent bond that releases a large amount of energy when hydrolyzed under the usual intracellular conditions. Examples include the phosphoanhydride bonds in ATP, thioester bond in acetyl CoA, and various phosphate ester bonds.

histone One of several small, highly conserved basic proteins, found in the **chromatin** of all eukaryotic cells, that associate with DNA in the **nucleosome**. (Figure 6-29)

Holliday structure An intermediate in DNA recombination with four DNA strands. (Figure 4-43)

homeodomain Conserved DNA-binding structural motif (a helix-turn-helix) found in many developmentally important transcription factors.

homologous See **homologs**.

homologous chromosome One of the two copies of each morphologic type of chromosome present in a **diploid** cell; also called **homolog**. Each homolog is derived from a different parent.

homologous recombination See **recombination**.

homologs Maternal and paternal copies of each morphologic type of chromosome present in a diploid cell; also called *homologues*.

homology Similarity in characteristics (e.g., protein and nucleic acid sequences or the structure of an organ) that reflects a common evolutionary origin. Proteins or genes that exhibit homology are said to be homologous and sometimes are called homologs. In contrast, *analogy* is a similarity in structure or function that does not reflect a common evolutionary origin.

homozygous Referring to a diploid cell or organism having two identical alleles of a particular gene.

hormone Generally, any extracellular substance that induces specific responses in target cells; specifically, those signaling molecules that circulate in the blood and mediate **endocrine** signaling.

hyaluronan A large, highly hydrated **glycosaminoglycan (GAG)** that is a major component of the extracellular matrix; also called *hyaluronic acid* and *hyaluronate*. It imparts stiffness and resilience as well as a lubricating quality to many types of connective tissue. (Figure 20-28a)

hybridization, nucleic acid Association of two complementary nucleic acid strands to form double-stranded molecules, which can contain two DNA strands, two RNA strands, or one DNA and one RNA strand. Used experimentally in various ways to detect specific DNA or RNA sequences.

hybridoma A clone of hybrid cells that are immortal and produce **monoclonal antibody**; formed by fusion of a normal antibody-producing B cell with a myeloma cell. (Figure 9-6)

hydrocarbon Any compound containing only carbon and hydrogen atoms.

hydrogen bond A **noncovalent interaction** between an atom (commonly oxygen or nitrogen) carrying a partial negative charge and a hydrogen atom carrying a partial positive charge. Important in stabilizing the conformation of proteins and in formation of **base pairs** between nucleic acid strands. (Figure 2-8)

hydrophilic Interacting effectively with water. See also **polar**.

hydrophobic Not interacting effectively with water; in general, poorly soluble or insoluble in water. See also **nonpolar**.

hydrophobic effect The tendency of nonpolar molecules or parts of molecules to associate with each other in aqueous solution so as to minimize their direct interactions with water; commonly called a *hydrophobic interaction* or *bond*. (Figure 2-11)

hyperpolarization Increase in the magnitude of the cytosolic-face negative electric potential that normally exists across the plasma membrane of a cell at rest, resulting in a more negative **membrane potential**.

hypertonic Referring to an external solution whose solute concentration is high enough to cause water to move out of cells due to **osmosis**.

hypotonic Referring to an external solution whose solute concentration is low enough to cause water to move into cells due to **osmosis**.

IgCAMs A family of **cell-adhesion molecules** that contain multiple immunoglobulin (Ig) domains and mediate Ca^{2+} -independent cell-cell interactions. IgCAMs are produced in a variety of tissues and are components of **tight junctions**. (Figure 20-2)

immunoblotting Technique in which proteins separated by electrophoresis are attached to a nitrocellulose or other membrane, and specific proteins then are detected by use of labeled antibodies; also called *Western blotting*.

immunoglobulin (Ig) Any of the serum proteins, produced by fully differentiated **B cells**, that can function as antibodies; also occur in membrane-bound form as part of the **B-cell receptor**. Immunoglobulins are divided into five main classes (*isotypes*) that exhibit distinct functional properties. See also **antibody**. (Figures 23-8 and 23-9)

immunoglobulin (Ig) fold Evolutionarily ancient structural motif found in antibodies, the T-cell receptor, and numerous other eukaryotic proteins not directly involved in antigen-specific recognition; also called *Ig domain*. (Figure 23-12b)

induced pluripotent stem (iPS) cells A mammalian cell with properties of an embryonic stem cell that is formed from a differentiated cell type by expression of one or more transcription factors or other genes that confer pluripotency.

inflammation Localized response to injury or infection that leads to the activation of immune-system cells and their recruitment to the affected site; marked by the four classical signs of redness, swelling, heat, and pain. (Figure 23-6)

inhibitory synapse A synapse in which the neurotransmitter induces a hyperpolarization of the postsynaptic cell, inhibiting generation of an action potential.

initiation, transcription The process by which an RNA polymerase separates DNA strands and synthesizes the first phosphodiester

bond of an RNA chain as templated by the DNA strand that enters the RNA polymerase active site. (Figure 4-11)

initiation factor (IF) One of a group of nonribosomal proteins that promote the proper association of ribosomes and mRNA and are required for initiation of **translation** (protein synthesis). (Figure 4-24)

initiator A DNA sequence that specifies transcription initiation within the sequence.

inner cell mass (ICM) The part of an early embryo that will form the embryo proper but not the extra-embryonic tissues, including the placenta.

inositol 1,4,5-trisphosphate (IP_3) Intracellular **second messenger** produced by cleavage of the membrane lipid phosphatidylinositol 4,5-bisphosphate in response to stimulation of certain cell-surface receptors. IP_3 , which triggers release of Ca^{2+} stored in the endoplasmic reticulum, is one of several biologically active **phosphoinositides**. (Figure 15-8; Table 15-3)

in situ hybridization Any technique for detecting specific DNA or RNA sequences in cells and tissues by treating samples with single-stranded RNA or DNA **probes** that hybridize to the sequence of interest. (Figure 5-28)

insulin A protein hormone produced in the β cells of the pancreatic islets that stimulates uptake of glucose into muscle and fat cells; acts with **glucagon** to help regulate blood glucose levels. Insulin also functions as a growth factor for many cells.

integral membrane protein Any protein that contains one or more hydrophobic segments embedded within the core of the **phospholipids bilayer**; also called *transmembrane protein*. (Figure 13-10)

integrins A large family of heterodimeric transmembrane proteins that function as adhesion receptors, promoting cell-matrix adhesion, or as cell-adhesion molecules, promoting cell-cell adhesion. (Table 20-3)

interferons (IFNs) Small group of cytokines that bind to cell-surface receptors on target cells inducing changes in gene expression that lead to an antiviral state or other cellular responses important in immune responses.

interleukins (ILs) Large group of cytokines, some released in response to inflammation, that promote proliferation and functioning of T cells and antibody-producing B cells of the immune system.

intermediate filament Cytoskeletal fiber (10 nm in diameter) formed by polymerization of related, but tissue-specific, subunit proteins, including **keratins**, **lamins**, and **neurofilaments**. (Figure 18-47; Table 18-1)

interneurons Nerves that receive signals from other nerve cells and that in turn transmit signals to other nerve cells.

interphase Long period of the cell cycle, including the G_1 , S, and G_2 phases, between one M (mitotic) phase and the next. (Figures 1-16 and 19-1)

intron Part of a **primary transcript** (or the DNA encoding it) that is removed by splicing during RNA processing and is not included in the mature, functional mRNA, rRNA, or tRNA.

ionic interaction A **noncovalent interaction** between a positively charged ion (cation) and negatively charged ion (anion); commonly called *ionic bond*.

IP₃ See inositol 1,4,5-trisphosphate.

isoelectric point (pI) The pH of a solution at which a dissolved protein or other potentially charged molecule has a net charge of zero and therefore does not move in an electric field. (Figure 3-37)

isoform One of several forms of the same protein whose amino acid sequences differ slightly and whose general activities are similar. Isoforms may be encoded by different genes or by a single gene whose primary transcript undergoes **alternative splicing**.

isotonic Referring to a solution whose solute concentration is such that it causes no net movement of water in or out of cells.

JAK kinase A class of protein tyrosine kinases that are bound to the cytosolic domain of cytokine receptors and are activated following cytokine binding.

karyopherin One of a family of nuclear transport proteins that functions as an **importin**, **exportin**, or occasionally both. Each karyopherin binds to a specific signal sequence in cargo proteins moving in or out of the nucleus.

karyotype Number, sizes, and shapes of the entire set of **metaphase** chromosomes of a eukaryotic cell. (Chapter 6 opening figure)

keratins A group of **intermediate filament** proteins found in epithelial cells that assemble into heteropolymeric filaments. (Figure 18-48)

kinase An enzyme that transfers the terminal (γ) phosphate group from ATP to a substrate. Protein kinases, which phosphorylate specific serine, threonine, or tyrosine residues, play a critical role in regulating the activity of many cellular proteins. See also **phosphatases**. (Figure 3-33)

kinesins A class of **motor proteins** that use energy released by ATP hydrolysis to move toward the (+) end of a **microtubule**. Kinesins can transport vesicles and organelles and play a role in chromosome movement during mitosis. (Figures 18-18 through 18-20)

kinetic energy Energy of movement, such as the motion of molecules.

kinetochore A multilayer protein structure located at or near the **centromere** of each mitotic chromosome from which microtubules extend toward the spindle poles of the cell; plays an active role in movement of chromosomes toward the poles during anaphase. (Figure 18-39)

K_m A parameter that describes the affinity of an enzyme for its substrate and equals the substrate concentration that yields the half-maximal reaction rate; also called the *Michaelis constant*. A similar parameter describes the affinity of a transport protein for the transported molecule or the affinity of a receptor for its ligand. (Figure 3-22)

knockdown, siRNA Technique for experimentally inhibiting translation of a specific mRNA by use of **siRNA**; useful for reducing the activity of a protein, particularly in organisms that are not amenable to classical genetic methods for isolating loss-of-function mutants.

knockout, gene Selective inactivation of a specific gene by replacing it with a nonfunctional (disrupted) allele in an otherwise normal organism.

lagging strand One of the two daughter DNA strands formed at a **replication fork** as short, discontinuous segments (Okazaki

fragments), which are synthesized in the 5' $\rightarrow$ 3' direction and later joined. See also **leading strand**. (Figure 4-30)

laminin Large heterotrimeric **multi-adhesive matrix protein** that is found in all **basal lamina**. (Figure 20-23)

lamins A group of **intermediate filament** proteins that form a fibrous network, the **nuclear lamina**, on the inner surface of the nuclear envelope.

late endosome See **endosome**.

lateral See **basolateral**.

lateral inhibition Important signal-mediated developmental process that results in adjacent equivalent or near-equivalent cells assuming different fates.

leading strand One of the two daughter DNA strands formed at a **replication fork** by continuous synthesis in the 5' $\rightarrow$ 3' direction. The direction of leading-strand synthesis is the same as movement of the replication fork. See also **lagging strand**. (Figure 4-30)

lectin Any protein that binds tightly to specific sugars. Lectins assist in the proper folding of some glycoproteins in the endoplasmic reticulum and can be used in affinity chromatography to purify glycoproteins or as reagents to detect them in situ.

leucine zipper A type of coiled-coil **structural motif** composed of two α helices that form specific homo- or heterodimers; common motif in many eukaryotic transcription factors. See **coiled coil**. (Figures 7-29c and 3-9)

ligand Any molecule, other than an enzyme **substrate**, that binds tightly and specifically to a macromolecule, usually a protein, forming a macromolecule-ligand complex.

linkage In genetics, the tendency of two different loci on the same chromosome to be inherited together. The closer two loci are, the lower the frequency of **recombination** between them and the greater their linkage.

lipid Any organic molecule that is poorly soluble or virtually insoluble in water but is soluble in nonpolar organic solvents. Major classes include **fatty acids**, **phospholipids**, **steroids**, and **triglycerides**.

lipid-anchored membrane protein Any protein that is tethered to a cellular membrane by one or more covalently attached lipid groups, which are embedded in the phospholipids bilayer. (Figure 10-19)

lipid raft Microdomain in the plasma membrane that is enriched in cholesterol, sphingomyelin, and certain proteins.

lipoprotein Any large, water-soluble protein and lipid complex that functions in mass transfer of lipids throughout the body. See also **low-density lipoprotein (LDL)**.

liposome Artificial spherical **phospholipid bilayer** structure with an aqueous interior that forms in vitro from phospholipids and may contain membrane proteins. (Figure 10-3c)

long terminal repeats (LTRs) Direct repeat sequences, containing up to 600 base pairs, that flank the coding region of integrated retroviral DNA and viral **retrotransposons**.

low-density lipoprotein (LDL) A class of **lipoprotein**, containing apolipoprotein B-100, that is a primary transporter of cholesterol in the form of cholesteryl esters between tissues, especially to the liver. (Figure 14-27)

lymphocytes Two classes of white blood cells that can recognize foreign molecules (**antigens**) and mediate immune responses. B lymphocytes (B cells) are responsible for production of antibodies; T lymphocytes (T cells) are responsible for destroying virus and bacteria-infected cells, foreign cells, and cancer cells.

lysis Destruction of a cell by rupture of the plasma membrane and release of the contents.

lysogeny Phenomenon in which the DNA of a bacterial virus (bacteriophage) is incorporated into the host-cell genome and replicated along with the bacterial DNA but is not expressed. Subsequent activation leads to formation of new viral particles, eventually causing lysis of the cell.

lysosome Small organelle that has an internal pH of 4–5, contains hydrolytic enzymes, and functions in degradation of materials internalized by endocytosis and of cellular components in autophagy. (Figures 9-12 and 9-32)

M (mitotic) phase See **cell cycle**.

macromolecule Any large, usually polymeric molecule (e.g., a protein, nucleic acid, polysaccharide) with a molecular mass greater than a few thousand daltons.

macrophages Phagocytic leukocytes that can detect broad patterns of pathogen markers via **Toll-like receptors**. They function as professional **antigen-presenting cells** and are a major source of cytokines.

major histocompatibility complex (MHC) Set of adjacent genes that encode class I and class II **MHC molecules** and other proteins required for antigen presentation, as well as some complement proteins; called the *H-2 complex* in mice and the *HLA complex* in humans. (Figure 23-19)

malignant Referring to a tumor or tumor cells that can invade surrounding normal tissue and/or undergo **metastasis**. See also **benign**.

MAP kinase Any of a family of protein kinases that are activated in response to cell stimulation by many different growth factors and that mediate cellular responses by phosphorylating specific transcription factors and other target proteins. (Figures 16-21 and 16-22)

matrix metalloproteases (MMPs) Matrix metalloproteases (MMPs) are proteolytic enzymes that employ the metal zinc in their active sites. They operate in the extracellular space, where they cut proteins in the extracellular matrix and sometimes other proteins (e.g., some cell-surface receptors).

maturation-promoting factor (MPF) Cyclin-CDK complex that has the ability to induce entry into meiosis when injected into G_2 -resting oocytes.

maximal velocity See V_{max} .

mechanosensor Any of several types of sensory structures that are embedded in various tissues and respond to touch, the positions and movements of the limbs and head, pain, and temperature.

mediator A very large multiprotein complex that forms a molecular bridge between transcriptional activators bound to an **enhancer** and to RNA polymerase II bound at a **promoter**; functions as a coactivator in stimulating transcription. (Figures 7-38 and 7-39)

meiosis In eukaryotes, a special type of cell division that occurs during maturation of germ cells; comprises two successive nuclear and cellular divisions with only one round of DNA replication. Results in production of four genetically nonequivalent haploid cells (**gametes**) from an initial diploid cell. (Figure 5-3)

membrane potential Electric potential difference, expressed in volts, across a membrane due to the slight excess of positive ions (cations) on one side and negative ions (anions) on the other. (Figures 11-18 and 11-19)

membrane transport protein Collective term for any integral membrane protein that mediates movement of one or more specific ions or small molecules across a cellular membrane regardless of the transport mechanism. (Figure 11-2)

memory The ability of an antigen-experienced immune system to respond more rapidly to a reexposure to that same antigenic stimulus.

meristem Organized group of undifferentiated, dividing cells that are maintained at the tips of growing shoots and roots in plants. All the adult structures arise from meristems.

merotelic attachment Indicates that a single kinetochore attaches to microtubules emanating from two opposite spindle poles.

mesenchymal stem cell A class of stem cells in the bone marrow that can differentiate into fat cells, osteoblasts (bone-forming cells), and cartilage-producing cells; some may also produce muscle and other types of differentiated cells.

mesenchyme Immature embryonic connective tissue, composed of loosely organized and loosely attached cells, derived from either the **mesoderm** or **ectoderm** in animals.

mesoderm The middle of the three primary cell layers of the animal embryo, lying between the **ectoderm** and **endoderm**; gives rise to the notochord, connective tissue, muscle, blood, and other tissues.

messenger RNA See **mRNA**.

metaphase Stage of mitosis at which condensed chromosomes are aligned equidistant between the poles of the mitotic spindle but have not yet started to segregate toward the spindle poles. (Figure 18-36)

metastasis Spread of cancer cells from their site of origin and establishment of areas of secondary growth.

metazoans A subset of the animal kingdom that includes all multicellular animals with differentiated tissues, such as nerves and muscles.

MHC See **major histocompatibility complex**.

MHC molecules Glycoproteins that display peptides, derived from foreign (and self) proteins, on the surface of cells and are required for antigen presentation to **T cells**. *Class I* molecules are expressed constitutively by nearly all nucleated cells; *class II* molecules, by professional antigen-presenting cells. (Figures 23-21 and 23-22)

micelle A water-soluble spherical aggregate of phospholipids or other amphipathic molecules that form spontaneously in aqueous solution. (Figure 10-3c)

Michaelis constant See K_m .

microfilament Cytoskeletal fiber (≈ 7 nm in diameter) that is formed by polymerization of monomeric globular (G) **actin**; also called *actin filament*. Microfilaments play an important role in

muscle contraction, cytokinesis, cell movement, and other cellular functions and structures. (Figure 17-4)

micro-RNA See **miRNA**.

microtubule Cytoskeletal fiber (≈ 25 nm in diameter) that is formed by polymerization of α , β -**tubulin** monomers and exhibits structural and functional polarity. Microtubules are important components of cilia, flagella, the mitotic spindle, and other cellular structures. (Figures 18-2 and 18-3)

microtubule-associated protein (MAP) Any protein that binds to microtubules and regulates their stability. (Figures 18-13, 18-14, and 18-15)

microtubule-organizing center See **MTOC**.

microvillus (pl. **microvilli**) Small, membrane-covered projection on the surface of an animal cell containing a core of actin filaments. Numerous microvilli are present on the absorptive surface of intestinal epithelial cells, increasing the surface area for transport of nutrients. (Figures 17-4 and 20-10)

miRNA (micro-RNA) Any of numerous small, endogenous cellular RNAs, 20–30 nucleotides long, that are processed from double-stranded regions of hairpin secondary structures in long precursor RNAs. A single strand of the mature miRNA associates with several proteins to form an RNA-induced silencing complex (**RISC**) that inhibits translation of a target mRNA to which the miRNA hybridizes imperfectly. Several miRNAs must hybridize to a single mRNA to inhibit its translation. See also **siRNA**. (Figures 8-25a and 8-26)

mitochondrion (pl. **mitochondria**) Large organelle that is surrounded by two phospholipid bilayer membranes, contains DNA, and carries out **oxidative phosphorylation**, thereby producing most of the ATP in eukaryotic cells. (Figures 9-33c and 12-6)

mitogen Any extracellular molecule, such as a growth factor, that promotes cell proliferation.

mitosis In eukaryotic cells, the process whereby the nucleus divides, producing two genetically equivalent daughter nuclei with the diploid number of chromosomes. See also **cytokinesis** and **meiosis**. (Figure 18-36)

mitotic CDKs Cyclin-CDK complexes that promote entry into and progression through mitosis.

mitotic spindle A specialized temporary structure, present in eukaryotic cells during mitosis, that captures the chromosomes and then pushes and pulls them to opposite sides of the dividing cell; also called *mitotic apparatus*. (Figure 18-37)

mobile DNA element See **transposable DNA element**.

model organism A non-human species used to study genes, proteins, and cellular functions. Model organisms are chosen based on the expectation that discoveries made via the model organism will provide insight into other organisms.

molecular chaperone See **chaperone**.

molecular complementarity Lock-and-key kind of fit between the shapes, charges, hydrophobicity, and/or other physical properties of two molecules or portions thereof that allow formation of multiple **oncovalent interactions** between them at close range. (Figure 2-12)

molecular markers, DNA-based DNA sequences that vary among individuals (*DNA polymorphisms*) of the same species and are useful in genetic linkage studies; includes SNPs and SSRs.

monoclonal antibody Antibody produced by the progeny of a single B cell and thus a homogeneous protein that recognizes a single antigen (epitope). It can be produced experimentally by use of a **hybridoma**. (Figure 9-6)

monomer Any small molecule that can be linked chemically with others of the same type to form a **polymer**. Examples include amino acids, nucleotides, and monosaccharides.

monomeric (small) G protein A monomeric GTPase with a structure similar to that of the Ras protein that changes conformation when a bound GTP is hydrolyzed to GDP and phosphate. (Figure 15-7)

monopolin complex Protein complex that promotes the co-orientation of sister chromatids during meiosis I in budding yeast.

monosaccharide Any simple sugar with the formula $(CH_2O)_n$, where $n = 3-7$.

monotelic attachment Indicates that only one of the sister kinetochore pair attached to microtubules.

monoubiquitination The covalent addition of a single ubiquitin molecule to a target protein.

motor protein Any member of a special class of mechanochemical enzymes that use energy from ATP hydrolysis to generate either linear or rotary motion; also called *molecular motor*. See also **dyneins**, **kinesins**, and **myosins**.

mRNA (messenger RNA) Any RNA that specifies the order of amino acids in a protein (i.e., the primary structure). It is produced by **transcription** of DNA by RNA polymerase. In eukaryotes, the initial RNA product (primary transcript) undergoes processing to yield functional mRNA. See also **translation**. (Figure 4-15)

mRNP-exporter A heterodimeric protein that binds to mRNA-containing ribonucleoprotein particles (mRNPs) and directs their export from the nucleus to cytoplasm by interacting transiently with **nucleoporins** in the nuclear pore complex. (Figure 8-22)

MTOC (microtubule-organizing center) General term for any structure (e.g., centrosome, spindle pole, basal body) that organizes microtubules in cells. (Figure 18-5)

mRNA surveillance The processes that lead to the degradation of a pre-mRNA or mRNA that has been improperly processed.

multi-adhesive matrix proteins Group of long flexible proteins that bind to other components of the **extracellular matrix** and to cell-surface receptors, thereby cross-linking matrix components to the cell membrane. Examples include **laminin**, a major component of the basal lamina, and **fibronectin**, present in many tissues.

multimeric For proteins, containing several polypeptide chains (or subunits).

multiubiquitination The covalent addition of several single ubiquitin molecules, each at a distinct site, on a single target protein.

MuSK A receptor tyrosine kinase localized in the myotube plasma membrane that both induces clustering of acetylcholine receptors and serves to attract the termini of growing motor neuron axons.

mutagen A chemical or physical agent that induces mutations.

mutation In genetics, a permanent, heritable change in the nucleotide sequence of a chromosome, usually in a single gene; commonly causes an alteration in the function of the gene product.

myelin sheath Stacked specialized cell membrane that forms an insulating layer around vertebrate **axons** and increases the speed of impulse conduction. (Figure 22-15)

myofibril Long, slender structures within cytoplasm of muscle cells consisting of a regular repeating array of **sarcomeres** composed of thick (**myosin**) filaments and thin (**actin**) filaments. (Figure 17-31)

myosins A class of **motor proteins** that have actin-stimulated ATPase activity. Myosins move along actin **microfilaments** during muscle contraction and cytokinesis and also mediate vesicle translocation. (Figure 17-22)

NAD⁺ (nicotinamide adenine dinucleotide) A small organic molecule that functions as an electron carrier by accepting two electrons from a donor molecule and one H⁺ from the solution. (Figure 2-33a)

NADP⁺ (nicotinamide adenine dinucleotide phosphate) Phosphorylated form of NAD⁺ that is used extensively as an electron carrier in biosynthetic pathways and during photosynthesis.

Na⁺/K⁺ ATPase A P-class ATP-powered pump that couples hydrolysis of one ATP molecule to export of Na⁺ ions and import of K⁺ ions; is largely responsible for maintaining the normal intracellular concentrations of Na⁺ (low) and K⁺ (high) in animal cells; commonly called *Na⁺/K⁺ pump*. (Figure 11-13)

natural killer (NK) cells Components of the innate immune system that nonspecifically detect and kill virus-infected cells and tumor cells. (Figure 23-5)

necrosis Cell death resulting from tissue damage or other pathology; usually marked by swelling and bursting of cells with release of their contents. Contrast with **apoptosis**.

negative feedback mechanism Process where the output of a pathway inhibits its own production.

neurofilaments (NFs) A group of **intermediate filament** proteins, found only in neurons, that contribute to axonal structure and rate of transmission of action potentials down axons. (Figure 18-2b)

neuron (nerve cell) Any of the impulse-conducting cells of the nervous system. A typical neuron contains a cell body; multiple short, branched processes (**dendrites**); and one long process (**axon**). (Figure 22-1)

neurotransmitter Extracellular signaling molecule that is released by the presynaptic neuron at a chemical **synapse** and relays the signal to the postsynaptic cell. The response elicited by a neurotransmitter, either excitatory or inhibitory, is determined by its receptor on the postsynaptic cell. (Figures 22-18 and 22-19)

neurotrophins Family of structurally and functionally related

trophic factors that bind to receptors called Trks and are required for survival of neurons; include nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF).

neutrophils Phagocytic leukocytes that are attracted to sites of tissue damage and migrate into the tissue. Once activated, neutrophils secrete various chemokines, cytokines, bacteria-destroying

enzymes (e.g., lysozyme), and other products that contribute to **inflammation** and help clear invading pathogens.

nicotinamide adenine dinucleotide See NAD⁺.

nicotinamide adenine dinucleotide phosphate See NADP⁺.

N-linked oligosaccharide A branched oligosaccharide chain attached to the side-chain amino group of an asparagine residue in a glycoprotein. See also **O-linked oligosaccharide**.

nociceptor Mechanosensor that responds to pain associated with injury to body tissues caused by mechanical trauma, heat, electricity, or toxic chemicals.

noncovalent interaction Any relatively weak chemical interaction that does not involve an intimate sharing of electrons. (Figures 2-6 and 2-12)

nonhomologous end joining (NHEJ) A pathway that repairs double-strand breaks in DNA in which the break ends are directly ligated without the need for a homologous template.

nonpolar Referring to a molecule or structure that lacks any net electric charge or asymmetric distribution of positive and negative charges. Nonpolar molecules generally are less soluble in water than polar molecules and are often water insoluble.

Northern blotting Technique for detecting specific RNAs separated by electrophoresis by hybridization to a labeled DNA **probe**. See also **Southern blotting**. (Figure 5-27)

nuclear body Roughly spherical, functionally specialized region in the nucleus, containing specific proteins and RNAs; many function in the assembly of ribonucleoprotein (RNP) complexes. The most prominent type is the **nucleolus**.

nuclear envelope Double-membrane structure surrounding the nucleus; the outer membrane is continuous with the endoplasmic reticulum and the two membranes are perforated by **nuclear pore complexes**. (Figure 9-32)

nuclear lamina Fibrous network on the inner surface of the nuclear envelope composed of lamin intermediate filaments. (Figure 19-22)

nuclear pore complex (NPC) Large, multiprotein structure, composed largely of nucleoporins, that extends across the nuclear envelope. Ions and small molecules freely diffuse through NPCs; large proteins and ribonucleoprotein particles are selectively transported through NPCs with the aid of soluble proteins. (Figure 13-33a and b)

nuclear receptor Member of a class of intracellular receptors that bind lipid-soluble molecules (e.g., steroid hormones), forming ligand-receptor complexes that activate transcription; also called *steroid receptor superfamily*. (Figure 7-44d)

nucleic acid A polymer of **nucleotides** linked by **phosphodiester bonds**. DNA and RNA are the primary nucleic acids in cells.

nucleic acid hybridization See **hybridization, nucleic acid**.

nucleocapsid A viral capsid plus the enclosed nucleic acid.

nucleolus Large structure in the nucleus of eukaryotic cells where rRNA synthesis and processing occurs and ribosome subunits are assembled. (Figure 6-33a)

nucleoporins Large group of proteins that make up the **nuclear pore complex**. One class (FG-nucleoporins) participates in nuclear import and export.

nucleoside A small molecule composed of a **purine** or **pyrimidine** base linked to a pentose (either ribose or deoxyribose). (Table 2-3)

nucleosome Structural unit of **chromatin** consisting of a disk-shaped core of **histone** proteins around which a 147-bp segment of DNA is wrapped. (Figure 6-29)

nucleotide A **nucleoside** with one or more phosphate groups linked via an ester bond to the sugar moiety, generally to the 5' carbon atom. DNA and RNA are polymers of nucleotides containing deoxyribose and ribose, respectively. (Figure 2-16 and Table 2-3)

nucleus Large membrane-bounded organelle in eukaryotic cells that contains DNA organized into chromosomes; synthesis and processing of RNA and ribosome assembly occur in the nucleus.

Okazaki fragments Short (<1000 bases), single-stranded DNA fragments that are formed during synthesis of the **lagging strand** in DNA replication and are rapidly joined by DNA ligase to form a continuous DNA strand. (Figure 4-30)

oligopeptide A small to medium-size linear polymer composed of amino acids connected by peptide bonds. The terms *peptide* and *oligopeptide* are often used interchangeably.

O-linked oligosaccharide Oligosaccharide chain that is attached to the side-chain hydroxyl group in a serine or threonine residue in a glycoprotein. See also *N-linked oligosaccharides*.

oncogene A gene whose product is involved either in transforming cells in culture or in inducing cancer in animals. Generally is a mutant form of a normal gene (**proto-oncogene**) for a protein involved in the control of cell growth or division. (Figure 24-11)

oncogene addiction Describes the observation that some cancers, despite containing numerous genetic abnormalities, depend on only a few genetic alteration to maintain their malignant phenotype. It is said that these cancers are "addicted" to certain oncogenic mutations.

oncoprotein A protein encoded by an **oncogene** that causes abnormal cell proliferation; may be a mutant unregulated form of a normal protein or a normal protein that is produced in excess or in the wrong time or place in an organism.

open reading frame (ORF) Region of sequenced DNA that is not interrupted by stop codons in one of the triplet reading frames. An ORF that begins with a start codon and extends for at least 100 codons has a high probability of encoding a protein.

operator Short DNA sequence in a bacterial or bacteriophage genome that binds a repressor protein and controls transcription of an adjacent gene. (Figure 7-3)

operon In bacterial DNA, a cluster of contiguous genes transcribed from one **promoter** that gives rise to an mRNA containing coding sequences for multiple proteins. (Figure 4-13a)

organelle Any membrane-limited subcellular structure found in eukaryotic cells. (Figures 1-12b, 9-32 and 9-33)

osmosis Net movement of water across a semipermeable membrane (permeable to water but not to solute) from a solution of lesser to one of greater solute concentration. (Figure 11-6)

oxidation Loss of electrons from an atom or molecule as occurs when a hydrogen atom is removed from a molecule or oxygen is added; opposite of **reduction**.

oxidation potential The voltage change when an atom or molecule loses an electron; a measure of the tendency of a molecule to lose an electron. For a given oxidation reaction, the oxidation potential has the same magnitude but opposite sign as the **reduction potential** for the reverse (reduction) reaction.

oxidative phosphorylation The phosphorylation of ADP to form ATP driven by the transfer of electrons to oxygen (O₂) in bacteria and mitochondria. Involves generation of a **proton-motive force** during electron transport and its subsequent use to power ATP synthesis.

p53 protein The product of a **tumor-suppressor gene** that plays a critical role in the arrest of cells with damaged DNA. Inactivating mutations in the *p53* gene are found in many human cancers. (Figure 24-26)

paracrine Referring to signaling mechanism in which a target cell responds to a signaling molecule (e.g., growth factor, neurotransmitter) that is produced by a nearby cell(s) and reaches the target by diffusion.

patch clamping Technique for determining ion flow through a single ion channel or across the membrane of an entire cell by use of a micropipette whose tip is applied to a small patch of the cell membrane. (Figure 11-22)

patterning genes Genes involved in metazoan development that determine the general organization of the animal, including the major body axes and segmentation.

P body Dense cytoplasmic domain, containing no ribosomes or translation factors, that functions in repression of translation and degradation of associated mRNAs; also called *cytoplasmic RNA-processing body*.

PCR (polymerase chain reaction) Technique for amplifying a specific DNA segment in a complex mixture by multiple cycles of DNA synthesis from short oligonucleotide primers followed by brief heat treatment to separate the complementary strands. (Figure 5-20)

pentose A five-carbon **monosaccharide**. The pentoses ribose and deoxyribose are present in RNA and DNA, respectively. (Figure 2-16)

peptide A small linear polymer composed of amino acids connected by peptide bonds. The terms *peptide* and *oligopeptide* are often used interchangeably. See also **polypeptide**.

peptide bond The covalent amide linkage between amino acids formed between the amino group of one amino acid and the carboxyl group of another with the net release of a water molecule (dehydration). (Figure 2-13)

peptidoglycan A polysaccharide chain cross-linked by peptide cross-bridges in a bacterial cell wall that confers rigidity and helps to determine the cell's shape.

pericentriolar material Amorphous material seen by thin-section electron microscopy surrounding the centrioles of animal cells. Pericentriolar material contains many components, including the gamma-tubulin ring complex (gamma-TuRC), which promotes nucleation of microtubule assembly. (Figure 18-6)

peripheral membrane protein Any protein that associates with the cytosolic or exoplasmic face of a membrane but does not enter the hydrophobic core of the phospholipid bilayer. See also **integral membrane protein**. (Figure 10-1)

perlecan A large multidomain **proteoglycan** component of the extracellular matrix (ECM) that binds to many ECM components, cell-surface molecules, and growth factors; a major component of the **basal lamina**.

peroxisome Small organelle that contains enzymes for degrading fatty acids and amino acids by reactions that generate hydrogen peroxide, which is converted to water and oxygen by catalase.

pH A measure of the acidity or alkalinity of a solution defined as the negative logarithm of the hydrogen ion concentration in moles per liter: $\text{pH} = -\log [\text{H}^+]$. Neutrality is equivalent to a pH of 7; values below this are acidic and those above are alkaline.

phagocyte Any cell that can ingest and destroy pathogens and other particulate antigens. The primary phagocytes are neutrophils, macrophages, and dendritic cells.

phagocytosis Process by which relatively large particles (e.g., bacterial cells) are internalized by certain eukaryotic cells in a process that involves extensive remodeling of the actin cytoskeleton; distinct from **receptor-mediated endocytosis**. (Figure 17-19)

phenotype The detectable physical and physiological characteristics of a cell or organism determined by its **genotype**; also, the specific trait associated with a particular allele.

pheromone A signaling molecule released by an individual that can alter the behavior or gene expression of other individuals of the same species. The yeast α and a mating-type factors are well-studied examples.

phosphatase An enzyme that removes a phosphate group from a substrate by hydrolysis. Phosphoprotein phosphatases act with protein kinases to control the activity of many cellular proteins. (Figure 3-33)

phosphoanhydride bond A type of **high-energy bond** formed between two phosphate groups, such as the γ and β phosphates and the β and α phosphates in ATP. (Figure 2-31)

phosphodiester bond Chemical linkage between adjacent nucleotides in DNA and RNA; consists of two phosphoester bonds, one on the 5' side of the phosphate and another on the 3' side. (Figure 4-2)

phosphoglycerides Amphipathic derivatives of glycerol 3-phosphate that generally consist of two hydrophobic fatty acyl chains esterified to the hydroxyl groups in glycerol and a polar head group attached to the phosphate; the most abundant lipids in biomembranes. (Figures 2-20 and 10-8a)

phosphoinositides A group of membrane-bound lipids containing phosphorylated inositol derivatives; some function as **second messengers** in several signal transduction pathways. (Figures 15-35 and 16-25)

phospholipase One of several enzymes that cleave various bonds in the hydrophilic end of **phospholipids**. (Figures 10-12)

phospholipase C (PLC) A membrane-associated phospholipase, activated by either G_{aq} or G_{uo} , that cleaves the membrane lipid phosphatidylinositol 4,5-bisphosphate to generate two second messengers, DAG and IP_3 . (Figures 15-35 and 15-36a)

phospholipid The major class of lipids present in biomembranes, including **phosphoglycerides** and **sphingolipids**. (Figures 10-8a, b and 2-20)

phospholipid bilayer A two-layer, sheet-like structure in which the polar head groups of phospholipids are exposed to the aqueous media on either side and the nonpolar fatty acyl chains are in the center; the foundation for all biomembranes. (Figure 10-3a, b)

phosphorylation The covalent addition of a phosphate group to a molecule such as a sugar or a protein. The hydrolysis of ATP often accompanies phosphorylation, providing energy to drive the reaction and the phosphate group that is covalently added to the target molecule. Enzymes that catalyze phosphorylation are called **kinases**.

photoelectron transport Light-driven electron transport that generates a charge separation across the **thylakoid membrane** that drives subsequent events in photosynthesis. (Figure 12-35)

photorespiration A reaction pathway that competes with CO_2 fixation (**Calvin cycle**) by consuming ATP and generating CO_2 , thus reducing the efficiency of photosynthesis. (Figure 12-47)

photosynthesis Complex series of reactions occurring in some bacteria and in plant **chloroplasts** in which light energy is used to generate carbohydrates from CO_2 , usually with the consumption of H_2O and evolution of O_2 .

photosystems Multiprotein complexes, present in all photosynthetic organisms, that consist of light-harvesting complexes containing **chlorophylls** and a reaction center where **photoelectron transport** occurs. (Figure 12-44a)

phragmoplast In plants, a temporary structure, formed during telophase, whose membranes become the plasma membranes of the daughter cells and whose contents develop into the new cell wall between them. (Figure 18-45)

pI See **isoelectric point**.

plakins A family of proteins that help attach **intermediate filaments** to other structures.

plaque assay Technique for determining the number of infectious viral particles in a sample by culturing a diluted sample on a layer of susceptible host cells and then counting the clear areas of lysed cells (plaques) that develop. (Figure 4-45)

plasma membrane The membrane surrounding a cell that separates the cell from its external environment; consists of a **phospholipids bilayer** and associated membrane lipids and proteins. (Figures 9-32, 10-1, and 10-5)

plasmid Small, circular extrachromosomal DNA molecule capable of autonomous replication in a cell; commonly used as a **vector** in **DNA cloning**.

plasmodesmata (sing. **plasmodesma**) Tube-like cell junctions that interconnect the cytoplasms of adjacent plant cells and are functionally analogous to **gap junctions** in animal cells. (Figure 20-41)

point mutation Change of a single nucleotide in DNA, especially in a region coding for protein; can result in formation of a codon specifying a different amino acid or a stop codon. Addition or deletion of a single nucleotide will cause a shift in the **reading frame**.

polar Referring to a molecule or structure with a net electric charge or asymmetric distribution of positive and negative charges. Polar molecules are usually soluble in water.

polarity In cell biology, the presence of functional and/or structural differences in distinct regions of a cell or cellular component.

polarized In cell biology, referring to any cell or subcellular structure marked by functional and structural asymmetries.

Polo kinases Family of protein kinases that are critical for many aspects of mitosis, such as centrosome duplication and cohesin removal from chromosomes.

polymer Any large molecule composed of multiple identical or similar units (**monomers**) linked by covalent bonds. (Figure 2-13)

polymerase chain reaction See **PCR**.

polypeptide Linear polymer of amino acids connected by peptide bonds, usually containing 20 or more residues. See also **protein**.

polyribosome A complex containing several **ribosomes**, all translating a single messenger RNA; also called *polysome*. (Figure 4-28)

polysaccharide Linear or branched polymer of **monosaccharides** linked by glycosidic bonds and usually containing more than 15 residues. Those with fewer than 15 residues are often called *oligosaccharides*.

polytene chromosome Enlarged chromosome composed of many parallel copies of itself formed by multiple cycles of DNA replication without chromosomal separation; found in the salivary glands and some other tissues of *Drosophila* and other dipteran insects. (Figure 6-43)

polyubiquitination The covalent addition of a chain of covalently linked ubiquitin molecules to a site on a target protein.

polyunsaturated Referring to a compound (e.g., fatty acid) in which two or more of the carbon-carbon bonds are double or triple bonds.

porins Class of trimeric transmembrane proteins through which small water-soluble molecules can cross the membrane; present in outer mitochondrial and chloroplast membranes and in the outer membrane of gram-negative bacteria. (Figure 10-18)

positive feedback mechanism Process where the output of a pathway promotes its own production.

potential energy Stored energy. In biological systems, the primary forms of potential energy are chemical bonds, concentration gradients, and electric potentials across cellular membranes.

pre-mRNA Precursor messenger RNA; the **primary transcript** and intermediates in RNA processing. (Figures 4-15 and 8-2)

pre-rRNA Large precursor ribosomal RNA that is synthesized in the nucleolus of eukaryotic cells and processed to yield three of the four RNAs present in ribosomes. (Figures 8-37 and 8-38)

primary structure In proteins, the linear arrangement (sequence) of amino acids within a polypeptide chain.

primary transcript In eukaryotes, the initial RNA product, containing **introns** and **exons**, produced by transcription of DNA. Many primary transcripts must undergo RNA processing to form the physiologically active RNA species.

primase A specialized RNA polymerase that synthesizes short stretches of RNA used as primers for DNA synthesis. (Figure 4-31).

primer A short nucleic acid sequence containing a free 3'-hydroxyl group that forms base pairs with a complementary template strand

and functions as the starting point for addition of nucleotides to copy the template strand.

probe Defined RNA or DNA fragment, radioactively, fluorescently, or chemically labeled, that is used to detect specific nucleic acid sequences by hybridization.

progenitor cells A type of undifferentiated cell that, when provided with the appropriate signals, will divide and differentiate into one or a few cell types.

programmed cell death See **apoptosis**.

prokaryotes Class of organisms, including the **bacteria** (eubacteria) and **archaea**, that lack a true membrane-limited nucleus and other organelles. See also **eukaryotes**. (Figure 1-1)

prometaphase Second stage in mitosis, during which the nuclear envelope and nuclear lamina break down and microtubules assembled from the spindle poles "capture" chromosome pairs at specialized structures called **kinetochores**. (Figure 18-36)

promoter DNA sequence that determines the site of **transcription** initiation for an RNA polymerase. (Figure 4-11)

promoter-proximal element Any regulatory sequence in eukaryotic DNA that is located within ≈ 200 base pairs of the transcription start site. Transcription of many genes is controlled by multiple promoter-proximal elements. (Figure 7-22)

prophase Earliest stage in mitosis, during which the chromosomes condense, the duplicated centrosomes separate to become the spindle poles, and the mitotic spindle begins to form. (Figure 18-36)

protease Any enzyme that cleaves one or more peptide bonds in target proteins.

proteasome Large multifunctional protease complex in the cytosol that degrades intracellular proteins marked for destruction by attachment of multiple **ubiquitin** molecules. (Figure 3-29)

protein A macromolecule composed of one or more linear **polypeptide** chains and folded into a characteristic three-dimensional shape (**conformation**) in its native, biologically active state.

protein family Set of homologous proteins encoded by a **gene family**.

protein domain Distinct regions of a protein's three-dimensional structure. A *functional* domain exhibits a particular activity characteristic of the protein; a *structural* domain is ≈ 40 or more amino acids in length, arranged in a distinct secondary or tertiary structure; a *topological* domain has a distinctive spatial relationship to the rest of the protein.

protein kinase A (PKA) Cytosolic enzyme that is activated by cyclic AMP (cAMP) and functions to phosphorylate and thus regulate the activity of numerous cellular proteins; also called *cAMP-dependent protein kinase*. (Figure 15-29)

protein kinase B (PKB) Cytosolic enzyme that is recruited to the plasma membrane by signal-induced **phosphoinositides** and subsequently activated; also called **Akt**. (Figure 16-26)

protein kinase C (PKC) Cytosolic enzyme that is recruited to the plasma membrane in response to signal-induced rise in cytosolic Ca^{2+} level and is activated by membrane-bound **diacylglycerol** (DAG). (Figure 15-36a)

protein kinase G (PKG) A cytosolic protein kinase activated by cyclic GMP.

proteoglycans A group of glycoproteins (e.g., perlecan and aggrecan) that contain a core protein to which is attached one or more **glycosaminoglycan (GAG)** chains. They are found in nearly all animal extracellular matrices, and some are integral membrane proteins. (Figure 20-31) **protome** The entire complement of proteins produced by a cell.

proteomics The systematic study of the amounts, modifications, interactions, localization, and functions of all or subsets of proteins at the whole-organism, tissue, cellular, and subcellular levels.

proton-motive force The energy equivalent of the proton (H^+) concentration gradient and electric potential gradient across a membrane; used to drive ATP synthesis by **ATP synthase**, transport of molecules against their concentration gradient, and movement of bacterial flagella. (Figure 12-2)

proto-oncogene A normal cellular gene that encodes a protein usually involved in regulation of cell growth or differentiation and that can be mutated into a cancer-promoting **oncogene**, either by changing the protein-coding segment or by altering its expression. (Figure 24-11)

protostomes A group of bilaterally symmetric animals whose mouth develops close to the blastopore and has a ventral nerve cord. This group includes worms, insects, and mollusks.

provirus The DNA of an animal virus that is integrated into a host-cell genome; during replication of the cell, the proviral DNA is replicated and appears in both daughter cells. Activation of proviral DNA leads to production and release of progeny virions.

pseudogene DNA sequence that is similar to that of a functional gene but does not encode a functional product; probably arose by sequence drift of duplicated genes.

pulse-chase A type of experiment in which a radioactive small molecule is added to a cell for a brief period (the pulse) and then is replaced with an excess of the unlabeled form of the same small molecule (the chase). Used to detect changes in the cellular location of a molecule or its metabolic fate over time. (Figure 3-40)

pump See **ATP-powered pump**.

purines A class of nitrogenous compounds containing two fused heterocyclic rings. Two purines, adenine (A) and guanine (G), are base components of nucleotides found in DNA and RNA. See also **base pair**. (Figure 2-17)

pyrimidines A class of nitrogenous compounds containing one heterocyclic ring. Two pyrimidines, cytosine (C) and thymine (T), are base components of nucleotides found in DNA; in RNA, uracil (U) replaces thymine. See also **base pair**. (Figure 2-17)

quaternary structure The number and relative positions of the polypeptide chains in multimeric (multisubunit) proteins. (Figure 3-10b)

radioisotope Unstable form of an atom that emits radiation as it decays. Several radioisotopes are commonly used experimentally as labels in biological molecules. (Table 3-1)

Ras protein A monomeric member of the **GTPase superfamily** of switch proteins that is tethered to the plasma membrane by a lipid anchor and functions in intracellular signaling pathways; activated by ligand binding to **receptor tyrosine kinases** and some other cell-surface receptors. (Figures 16-17 and 16-19)

rate constant A constant that relates the concentrations of reactants to the rate of a chemical reaction.

Rb protein Inhibitor of the E2F transcription factor family and thus a key regulator of cell cycle entry.

reading frame The sequence of nucleotide triplets (**codons**) that runs from a specific translation start codon in an mRNA to a stop codon. Some mRNAs can be translated into different polypeptides by reading in two different reading frames. (Figure 4-18)

receptor Any protein that specifically binds another molecule to mediate cell-cell signaling, adhesion, endocytosis, or other cellular process. Commonly denotes a protein located in the plasma membrane, cytosol, or nucleus that binds a specific extracellular molecule (**ligand**), which often induces a conformational change in the receptor, thereby initiating a cellular response. See also **adhesion receptor** and **nuclear receptor**. (Figures 15-1 and 16-1)

receptor-mediated endocytosis Uptake of extracellular materials bound to specific cell-surface receptors by invagination of the plasma membrane to form a small membrane-bounded vesicle (early endosome). (Figure 14-29)

receptor tyrosine kinase (RTK) Member of a large class of cell-surface receptors, usually with a single transmembrane domain, including those for insulin and many growth factors. Ligand binding activates tyrosine-specific protein kinase activity in the receptor's cytosolic domain, thereby initiating intracellular signaling pathways. (Figures 16-3 and 16-4)

recessive In genetics, referring to that allele of a gene that is not expressed in the **phenotype** when the **dominant** allele is present; also refers to the phenotype of an individual (homozygote) carrying two recessive alleles. Mutations that produce recessive alleles generally result in a loss of the gene's function. (Figure 5-2)

recombinant DNA Any DNA molecule formed in vitro by joining DNA fragments from different sources.

recombination Any process in which chromosomes or DNA molecules are cleaved and the fragments are rejoined to give new combinations. Homologous recombination occurs during meiosis, giving rise to **crossing over** of homologous chromosomes. Homologous recombination and nonhomologous recombination (i.e., between chromosomes of different morphologic type) also occur during several DNA-repair mechanisms and can be carried out in vitro with purified DNA and enzymes. (Figure 5-10)

redox reaction An oxidation-reduction reaction in which one or more electrons are transferred from one reactant to another.

reduction Gain of electrons by an atom or molecule as occurs when a hydrogen atom is added to a molecule or oxygen is removed. The opposite of **oxidation**.

reduction potential (E) The voltage change when an atom or molecule gains an electron; a measure of the tendency of a mole-

cule to gain an electron. For a given reduction reaction, E has the same magnitude but opposite sign as the **oxidation potential** for the reverse (oxidation) reaction.

release factor (RF) One of two types of nonribosomal proteins that recognize stop codons in mRNA and promote release of the completed polypeptide chain, thereby terminating **translation** (protein synthesis). (Figure 4-27)

replication fork Y-shaped region in double-stranded DNA at which the two strands are separated and replicated during DNA synthesis; also called *growing fork*. (Figure 4-30)

replication origin Unique DNA segment present in an organism's genome at which DNA replication begins. Eukaryotic chromosomes contain multiple origins, whereas bacterial chromosomes and plasmids usually contain just one.

reporter gene A gene encoding a protein that is easily assayed (e.g., β -galactosidase, luciferase). Reporter genes are used in various types of experiments to indicate activation of the promoter to which the reporter gene is linked.

repression domain A region of a repressor transcription factor that will inhibit transcription when fused to a DNA-binding domain.

repressor Specific **transcription factor** that inhibits transcription.

residue General term for the repeating units in a polymer that remain after covalent linkage of the monomeric precursors.

resolution The minimum distance between two objects that can be distinguished by an optical apparatus; also called *resolving power*.

respiration The conversion of energy in nutrients into ATP via a set of reactions involving a series of protein-catalyzed, membrane-associated oxidation and reduction reactions, called an electron transport chain, that are ultimately coupled to the addition of P_i to ADP (oxidative phosphorylation) to form ATP and transfer of electrons to oxygen or other inorganic electron acceptors.

respiratory chain See **electron transport chain**.

respiratory control Dependence of mitochondrial oxidation of NADH and $FADH_2$ on the supply of ADP and P_i for ATP synthesis.

resting K^+ channels Nongated K^+ ion channels in the plasma membrane that, in conjunction with the high cytosolic K^+ concentration produced by the Na^+/K^+ ATPase, are primarily responsible for generating the inside-negative resting **membrane potential** in animal cells.

restriction enzyme Any enzyme that recognizes and cleaves a specific short sequence, the *restriction site*, in double-stranded DNA molecules; used extensively to produce **recombinant DNA** in vitro; also called *restriction endonuclease*. (Figure 5-11; Table 5-1)

retrotransposon Type of eukaryotic **transposable DNA element** whose movement in the genome is mediated by an RNA intermediate and involves a reverse-transcription step. See also **transposon**. (Figure 6-8b)

retrovirus Type of eukaryotic virus containing an RNA genome that replicates in cells by first making a DNA copy of the RNA.

This viral DNA is inserted into cellular chromosomal DNA, forming a **provirus**, and gives rise to further genomic RNA as well as the mRNAs for viral proteins. (Figure 4-49)

reverse transcriptase Enzyme found in retroviruses that catalyzes a complex reaction in which a double-stranded DNA is synthesized from a single-stranded RNA template. (Figure 6-14)

R group A portion of a molecule, or a chemical group within a larger molecule, that is covalently bonded as an appendage to the main body or core of the molecule. In an amino acid, the R group is the side chain that is attached to the alpha carbon atom and that confers the distinct characteristics of the amino acid.

ribonucleic acid (RNA) See **RNA**.

ribonucleoprotein (RNP) complex General term for any complex composed of proteins and RNA. Most RNA molecules are present in the cell in the form of RNPs.

ribosome A large complex comprising several different **rRNA** molecules and as many as 83 proteins, organized into a large subunit and small subunit; the engine of **translation** (protein synthesis). (Figures 4-22 and 4-23)

ribosomal RNA See **rRNA**.

ribozyme An RNA molecule with catalytic activity. Ribozymes function in RNA splicing and protein synthesis.

ribulose 1,5-bisphosphate carboxylase Enzyme located in chloroplasts that catalyzes the first reaction in the **Calvin cycle**, the addition of CO_2 to a five-carbon sugar (ribulose 1,5-bisphosphate) to form two molecules of 3-phosphoglycerate; also called *rubisco*. (Figure 12-45)

RISC See **RNA-induced silencing complex**.

RNA (ribonucleic acid) Linear, single-stranded polymer, composed of ribose **nucleotides**. mRNA, rRNA, and tRNA play different roles in protein synthesis; a variety of small RNAs play roles in controlling the stability and translation of mRNAs and in controlling chromatin structure and transcription. (Figure 4-17)

RNA editing Unusual type of RNA processing in which the sequence of a pre-mRNA is altered.

RNA-induced silencing complex (RISC) Large multiprotein complex associated with a short single-stranded RNA (siRNA or miRNA) that mediates degradation or translational repression of a complementary or near-complementary mRNA.

RNA interference (RNAi) Functional inactivation of a specific gene by a corresponding double-stranded RNA that induces either inhibition of translation or degradation of the complementary single-stranded mRNA encoded by the gene but not that of mRNAs with a different sequence. (Figures 5-45)

RNA polymerase An enzyme that copies one strand of DNA (the *template strand*) to make the **complementary RNA** strand using as substrates ribonucleoside triphosphates. (Figure 4-11)

RNA splicing A process that results in removal of **introns** and joining of **exons** in pre-mRNAs. See also **spliceosome**. (Figures 8-8 and 8-9)

rRNA (ribosomal RNA) Any one of several large RNA molecules that are structural and functional components of **ribosomes**.

Often designated by their sedimentation coefficient: 28S, 18S, 5.8S, and 5S rRNA in higher eukaryotes. (Figure 4-22)

rubisco See **ribulose 1,5-bisphosphate carboxylase**.

S (synthesis) phase See **cell cycle**.

sarcomere Repeating structural unit of striated (skeletal) muscle composed of organized, overlapping thin (**actin**) filaments and thick (**myosin**) filaments and extending from one Z disk to an adjacent one; shortens during contraction. (Figures 17-31 and 17-32)

sarcoplasmic reticulum Network of membranes in cytoplasm of a muscle cell that sequesters Ca^{2+} ions; release of stored Ca^{2+} induced by muscle stimulation triggers contraction. (Figure 17-34)

satellite DNA See **simple-sequence DNA**.

saturated Referring to a compound (e.g., fatty acid) in which all the carbon-carbon bonds are single bonds.

SCF (Skp1, Cullin, F-box proteins) Ubiquitin-protein ligase that ubiquitinylates inhibitors of S-phase CDKs and many other proteins, marking them for degradation by proteasomes.

second messenger A small intracellular molecule (e.g., cAMP, cGMP, Ca^{2+} , DAG, and IP_3) whose concentration increases (or decreases) in response to binding of an extracellular signal and that functions in **signal transduction**. (Figure 15-8)

secondary structure In proteins, local folding of a polypeptide chain into regular structures including the α helix, β sheet, and β turns.

secretory pathway Cellular pathway for synthesizing and sorting soluble and membrane proteins localized to the endoplasmic reticulum, Golgi, and lysosomes; plasma membrane proteins; and proteins eventually secreted from the cell. (Figure 14-1)

segregation The process that distributes an equal complement of chromosomes to daughter cells during mitosis and meiosis.

selectins A family of **cell-adhesion molecules** that mediate Ca^{2+} -dependent interactions with specific oligosaccharide moieties in glycoproteins and glycolipids on the surface of adjacent cells or in extracellular glycoproteins. (Figures 20-2 and 20-39)

sensor Measures an intra- or extracellular property and converts into a signal.

shuttle vector Plasmid vector capable of propagation in two different hosts. (Figure 5-17)

side chain In amino acids, the variable substituent group attached to the **alpha (α) carbon atom** that largely determines the particular properties of each amino acid; also called *R group*. (Figure 2-14)

signaling cascade Pathway that is activated by an intracellular or extracellular event and then transmits the signal to an **effector**.

signaling molecule General term for any extracellular or intracellular molecule involved in mediating the response of a cell to its external environment or to other cells.

signal-recognition particle (SRP) A cytosolic ribonucleoprotein particle that binds to the ER **signal sequence** in a nascent secretory protein and delivers the nascent chain/ribosome complex to the ER membrane, where synthesis of the protein and translocation into the ER are completed. (Figure 13-5)

signal sequence A relatively short amino acid sequence within a protein that directs the protein to a specific location within the cell; also called *signal peptide* and *uptake-targeting sequence*. (Table 13-1)

signal transduction Conversion of a signal from one physical or chemical form into another. In cell biology commonly refers to the sequential process initiated by binding of an extracellular signal to a receptor and culminating in one or more specific cellular responses.

silencer A sequence in eukaryotic DNA that promotes formation of condensed chromatin structures in a localized region, thereby blocking access of proteins required for transcription of genes within several hundred base pairs of the silencer; also called *silencer sequence*.

simple diffusion Net movement of a molecule across a membrane down its concentration gradient at a rate proportional to the gradient and the permeability of the membrane; also called *passive diffusion*.

simple-sequence DNA Short, tandemly repeated sequences that are found at **centromeres** and **telomeres** as well as at other chromosomal locations and are not transcribed; also called *satellite DNA*.

siRNA A small, double-stranded RNA, 21–23 nucleotides long with two single-stranded nucleotides at each end. A single strand of the siRNA associates with several proteins to form an **RNA-induced silencing complex (RISC)** that cleaves target RNAs to which the siRNA base pairs perfectly; variously called *short* or *small interfering RNA* and *small inhibitory RNA*. siRNAs can be designed to experimentally inhibit expression of specific genes. See also **miRNA**. (Figure 8-25b)

siRNA knockdown A procedure that induces the degradation of a specific RNA by transfecting cells with double-stranded RNA having one strand with the same sequence as the target RNA. This double-stranded RNA is called an siRNA for “short-interfering RNA.”

sister chromatid resolution The process of untangling of the intertwined **sister chromatids** during prophase.

sister chromatids The two identical DNA molecules created during DNA replication and the associated chromosomal proteins. After DNA replication, each chromosome is composed of two sister chromatids.

Smads Class of transcription factors that are activated by phosphorylation following binding of members of the **transforming growth factor β (TGF β)** family of signaling molecules to their cell-surface receptors. (Figure 16-28)

SMC proteins Structural maintenance of chromosome proteins; a small family of nonhistone chromatin proteins that are critical for maintaining the morphological structure of chromosomes and their proper segregation during mitosis. Members of this family include *condensins*, which help condense chromosomes during mitosis, and *cohesins*, which link **sister chromatids** until their

separation in anaphase. Bacterial SMC proteins function in the proper segregation of bacterial chromosomes to daughter cells. (Figures 6-36 and 19-27)

SNAREs Cytosolic and integral membrane proteins that promote fusion of vesicles with target membranes. Interaction of v-SNAREs on a vesicle with cognate t-SNAREs on a target membrane forms very stable complexes, bringing the vesicle and target membranes into close apposition. (Figure 14-10)

snoRNA (small nucleolar RNA) A type of small, stable RNA that functions in rRNA processing and base modification in the nucleolus.

snRNA (small nuclear RNA) One of several small, stable RNAs localized to the nucleus. Five snRNAs are components of the spliceosome and function in splicing of pre-mRNA. (Figures 8-9 and 8-11)

somatic cell Any plant or animal cell other than a germ cell.

sorting signal A relatively short amino acid sequence within a protein that directs the protein to particular transport vesicles as they bud from a donor membrane in the secretory or endocytic pathway. (Table 14-2)

Southern blotting Technique for detecting specific DNA sequences separated by electrophoresis by hybridization to a labeled nucleic acid probe. (Figure 5-26)

specificity The ability of immune cells or their products to distinguish between structurally closely related molecules.

sperm The male gamete—a motile haploid cell that can bind to and fuse with an egg cell, forming a zygote.

S-phase CDKs Cyclin-CDK complexes that promote the initiation of DNA replication.

sphingolipid Major group of membrane lipids, derived from sphingosine, that contain two long hydrocarbon chains and either a phosphorylated head group (sphingomyelin) or carbohydrate head group (cerebrosides, gangliosides). (Figure 10-8b)

spindle assembly checkpoint pathway Pathway that senses incorrect attachment of chromosomes to the mitotic spindle and induces cell cycle arrest in metaphase.

spindle midzone Middle portion of the mitotic spindle that plays an important role in cleavage furrow positioning in some organisms.

spindle pole bodies Functionally analogous structure of centrosomes in yeast.

spindle position checkpoint pathway Pathway that senses incorrect position of the mitotic spindle within the cell and induces cell cycle arrest in anaphase.

spliceosome Large ribonucleoprotein complex that assembles on a pre-mRNA and carries out RNA splicing. (Figure 8-11)

SRE-binding proteins (SREBPs) Cholesterol-dependent transcription factors, localized in the ER membrane, that are activated in response to low cellular cholesterol levels and then stimulate expression of genes encoding proteins involved in cholesterol synthesis and import as well as synthesis of other lipids. (Figure 16-37)

starch A very long, branched polysaccharide, composed exclusively of glucose units, that is the primary storage carbohydrate in plant cells. (Figure 12-30)

START Point in the cell cycle at which cells are irreversibly committed to cell division and can no longer return to the G₁ state.

steady state In cellular metabolic pathways, the condition when the rate of formation and rate of consumption of a substance are equal, so that its concentration remains constant. (Figure 2-23)

stem cell A self-renewing cell that can divide *symmetrically* to give rise to two daughter cells whose developmental potential is identical to that of the parental stem cell or *asymmetrically* to generate daughter cells with different developmental potentials. (Figure 21-8)

stem-cell niche A set of cells, extracellular matrices, and hormones that surrounds a stem cell and that maintains its stem-cell properties

stereoisomers Two compounds with identical molecular formulas whose atoms are linked in the same order but in different spatial arrangements. In *optical isomers*, designated D and L, the atoms bonded to an **asymmetric carbon atom** are arranged in a mirror-image fashion. *Geometric isomers* include the *cis* and *trans* forms of molecules containing a double bond.

steroids A group of four-ring hydrocarbons including cholesterol and related compounds. Many important hormones (e.g., estrogen and progesterone) are steroids. *Sterols* are steroids containing one or more hydroxyl groups. (Figure 10-8c)

structural motif A particular combination of two or more secondary structures that form a distinct three-dimensional structure that appears in multiple proteins and that often, but not always, is associated with a specific function.

substrate Molecule that undergoes a change in a reaction catalyzed by an enzyme.

substrate-level phosphorylation Formation of ATP from ADP and P_i catalyzed by cytosolic enzymes in reactions that do not depend on a proton-motive force or molecular oxygen.

sulfhydryl group (—SH) A substituent group present in the amino acid cysteine and other molecules consisting of a hydrogen atom covalently bonded to a sulfur atom; also called a *thiol group*.

symmetric cell division See **cell division**.

symport A type of **cotransport** in which a membrane protein (*symporter*) transports two different molecules or ions across a cell membrane in the *same* direction. See also **antiport**. (Figure 11-2, [3B])

synapse Specialized region between an axon terminal of a neuron and an adjacent neuron or other excitable cell (e.g., muscle cell) across which impulses are transmitted. At a *chemical synapse*, the impulse is conducted by a **neurotransmitter**; at an *electric synapse*, impulse transmission occurs via **gap junctions** connecting the pre- and postsynaptic cells. (Figure 22-3)

synaptic vesicles Small vesicles in axon termini that contain a neurotransmitter and that undergo exocytosis following arrival of an action potential.

synaptonemal complex (SC) Proteinaceous structure that mediates the association (synapsis) between homologous chromosomes during prophase of meiosis I.

syndecans A class of cell-surface **proteoglycans** that function in cell-matrix adhesion, interact with the cytoskeleton, and may bind external signals, thereby participating in cell-cell signaling.

syntelic attachment Indicates that kinetochores of a **sister chromatid** pair attach to microtubules emanating from the same pole.

synteny Occurrence of genes in the same order on a chromosome in two or more different species.

TATA box A conserved sequence in the **promoter** of many eukaryotic protein-coding genes where the transcription-initiation complex assembles. (Figure 7-14)

T cell A lymphocyte that matures in the thymus and expresses antigen-specific receptors that bind antigenic peptides complexed to **MHC molecules**. There are two major classes: *cytotoxic* T cells (CD8 surface marker, class I MHC restricted, kill virus-infected and tumor cells) and *helper* T cells (CD4 marker, class II MHC restricted, produce cytokines, required for activation of B cells). (Figures 23-32 and 23-35)

T-cell receptor A heterodimeric antigen-binding transmembrane protein containing variable and constant regions and associated with the signal-transducing multimeric CD3 complex. (Figure 23-27)

telomere Region at each end of a eukaryotic chromosome containing multiple tandem repeats of a short telomeric (TEL) sequence. Telomeres are required for proper chromosome segregation and are replicated by a special process that prevents shortening of chromosomes during DNA replication. (Figure 6-47)

telophase Final mitotic stage, during which the nuclear envelope re-forms around the two sets of separated chromosomes, the chromosomes decondense, and division of the cytoplasm (cytokinesis) is completed. (Figure 18-36)

temperature-sensitive (ts) mutation A mutation that produces a wild-type phenotype at one temperature (the permissive temperature) but a mutant phenotype at another temperature (the non-permissive temperature). This type of mutation is especially useful in identification of genes essential for life. (Figure 5-6)

termination, transcription Cessation of the synthesis of an RNA chain. (Figure 4-11)

tertiary structure In proteins, overall three-dimensional form of a polypeptide chain, which is stabilized by multiple noncovalent interactions between side chains. (Figure 3-10a)

thylakoids Flattened membranous sacs in a chloroplast that can be arranged in stacks and contain the photosynthetic pigments and **photosystems**. (Figure 12-31)

tight junction A type of cell-cell junction between the plasma membranes of adjacent epithelial cells that prevents diffusion of macromolecules and many small molecules and ions in the spaces between cells and diffusion of membrane components between the apical and basolateral regions of the plasma membrane. (Figure 20-16)

tolerance The absence of an immune response to a particular antigen or set of antigens.

Toll-like receptor (TLR) Member of a class of cell-surface and intracellular receptors that recognize a variety of microbial products. Ligand binding initiates a signaling pathway that induces various responses depending on the cell type. (Figure 23-33)

topogenic sequences Segments within a protein whose sequence, number, and arrangement direct the insertion and orientation of various classes of transmembrane proteins into the endoplasmic reticulum membrane. (Figure 13-14)

transcription Process in which one strand of a DNA molecule is used as a template for synthesis of a **complementary** RNA by RNA polymerase. (Figures 4-10 and 4-11)

transcription-control region Collective term for all the DNA regulatory sequences that regulate transcription of a particular gene.

transcription factor (TF) General term for any protein, other than RNA polymerase, required to initiate or regulate transcription in eukaryotic cells. *General* factors, required for transcription of all genes, participate in formation of the transcription-preinitiation complex near the start site. *Specific* factors stimulate (**activators**) or inhibit (**repressors**) transcription of particular genes by binding to their regulatory sequences.

transcription unit A region in DNA, bounded by an initiation (start) site and termination site, that is transcribed into a single **primary transcript**.

transcytosis Mechanism for transporting certain substances across an epithelial sheet that combines **receptor-mediated endocytosis** and **exocytosis**. (Figures 14-25 and 23-10)

transfection Experimental introduction of foreign DNA into cells in culture, usually followed by expression of genes in the introduced DNA. (Figure 5-32)

transfer RNA See **tRNA**.

transformation (1) Permanent, heritable alteration in a cell resulting from the uptake and incorporation of a foreign DNA into the host-cell genome; also called *stable transfection*. (2) Conversion of a "normal" mammalian cell into a cell with cancer-like properties usually induced by treatment with a virus or other cancer-causing agent.

transforming growth factor beta (TGF β) A family of secreted signaling proteins that are used in the development of most tissues in most or all animals. Members of the TGF β family more often inhibit growth than stimulate it. Mutations in TGF β signal transduction components are implicated in human cancer, including breast cancer. (Figures 16-27 and 16-28)

transgene A cloned gene that is introduced and stably incorporated into a plant or animal and is passed on to successive generations.

trans-Golgi network (TGN) Complex network of membranes and vesicles that serves as a major branch point in the **secretory pathway**. Vesicles budding from this most-distal Golgi compartment carry membrane and soluble proteins to the cell surface or to lysosomes. (Figures 14-1 and 14-17)

transition state State of the reactants during a chemical reaction when the system is at its highest energy level; also called the **transition-state intermediate**.

translation The ribosome-mediated assembly of a polypeptide whose amino acid sequence is specified by the nucleotide sequence in an mRNA. (Figure 4-17)

translocon Multiprotein complex in the membrane of the rough endoplasmic reticulum through which a nascent secretory protein enters the ER lumen as it is being synthesized. (Figure 13-7)

transporters Membrane proteins that undergo conformational changes as they move a wide variety of ions and molecules across cell membranes at a slower rate than channels. See *uniporter*, *symporter*, and *antiporter* in Figure 11-3.

transport protein See *membrane transport protein*.

transport vesicle A small membrane-bounded compartment that carries soluble and membrane “cargo” proteins in the forward or reverse direction in the **secretory pathway**. Vesicles form by budding off from the donor organelle and release their contents by fusion with the target membrane.

transposable DNA element Any DNA sequence that is not present in the same chromosomal location in all individuals of a species and can move to a new position by **transposition**; also called *mobile DNA element* and *interspersed repeat*. (Table 6-1)

transposition Movement of a **transposable DNA element** within the genome; occurs by a cut-and-paste mechanism or copy-and-paste mechanism depending on the type of element. (Figure 6-8)

transposon, DNA A **transposable DNA element** present in prokaryotes and eukaryotes that moves in the genome by a mechanism involving DNA synthesis and transposition. See also *retrotransposon*. (Figures 6-9 and 6-10)

triacylglycerol See *triglyceride*.

triglyceride Major form in which fatty acids are stored and transported in animals; consists of three fatty acyl chains esterified to a glycerol molecule.

trimeric (large) G. protein A regulatory membrane-associated GTPase consisting of a catalytic α subunit and a β and γ subunit. When the α subunit is bound to GTP, the β and γ subunits dissociate as a heterodimer. The free α subunit and the free β - γ heterodimer can then interact with other proteins and transduce a signal across the membrane. When the α subunit hydrolyzes the GTP to GDP and phosphate, the α -GDP associates with the β - γ heterodimer, terminating signaling. (Figure 15-17)

tRNA (transfer RNA) A group of small RNA molecules that function as amino acid donors during protein synthesis. Each tRNA becomes covalently linked to a particular amino acid, forming an **aminoacyl-tRNA**. (Figures 4-19 and 4-20)

trophic factor Any of numerous signaling proteins required for the survival of cells in multicellular organisms; in the absence of such signals, cells often undergo “suicide” by **apoptosis**.

trophoblast The part of an early mammalian embryo that will form the extra-embryonic tissues, including the placenta but not the embryo proper.

t-SNAREs See **SNAREs**.

tubulin A family of globular cytoskeletal proteins that polymerize to form the cylindrical wall of **microtubules**. (Figure 18-3)

tumor A mass of cells, generally derived from a single cell, that arises due to loss of the normal regulators of cell growth; may be **benign** or **malignant**.

tumor-suppressor gene Any gene whose encoded protein directly or indirectly inhibits progression through the cell cycle and in which a loss-of-function mutation is oncogenic. Inheritance of a single mutant allele of many tumor-suppressor genes (e.g., *RB*, *APC*, and *BRCA1*) greatly increases the risk for developing colorectal and other types of cancer. (Figures 24-8 and 24-11)

ubiquitin A small protein that can be covalently linked to other intracellular proteins, thereby tagging these proteins for degradation by the **proteasome**, sorting to the lysosome, or alteration in the function of the target protein. (Figure 3-29)

uncoupler Any natural substance (e.g., the protein thermogenin) or chemical agent (e.g., 2,4-dinitrophenol) that dissipates the **proton-motive force** across the inner mitochondrial membrane or thylakoid membrane of chloroplasts, thereby inhibiting ATP synthesis.

unsaturated Referring to a compound (e.g., fatty acid) in which one of the carbon-carbon bonds is a double or triple bond.

upstream (1) For a gene, the direction opposite to that in which RNA polymerase moves during transcription. Nucleotides upstream from the +1 position (the first transcribed nucleotide) are designated -1, -2, etc. (2) Events that occur earlier in a cascade of steps (e.g., signaling pathway). See also **downstream**.

upstream activating sequence (UAS) Any protein-binding regulatory sequence in the DNA of yeast and other simple eukaryotes that is necessary for maximal gene expression; equivalent to an enhancer or promoter-proximal element in higher eukaryotes. (Figure 7-22)

vaccine An innocuous preparation derived from a pathogen and designed to elicit an immune response in order to provide immunity against a future challenge by a virulent form of the same pathogen.

van der Waals interaction A weak **noncovalent interaction** due to small, transient asymmetric electron distributions around atoms (dipoles). (Figure 2-10)

vector In cell biology, an autonomously replicating genetic element used to carry a cDNA or fragment of genomic DNA into a host cell for the purpose of gene cloning. Commonly used vectors are bacterial plasmids and modified bacteriophage genomes. See also **expression vector** and **shuttle vector**. (Figure 5-13)

viral envelope A phospholipid bilayer forming the outer covering of some viruses (e.g., influenza and rabies viruses); is derived by budding from a host-cell membrane and contains virus-encoded glycoproteins. (Figure 4-47)

virion An individual viral particle.

virus A small intracellular parasite, consisting of nucleic acid (RNA or DNA) enclosed in a protein coat, that can replicate only in a susceptible host cell; widely used in cell biology research. (Figure 4-44)

V_{max} Parameter that describes the maximal velocity of an enzyme-catalyzed reaction or other process such as protein-mediated transport of molecules across a membrane. (Figures 3-22 and 11-4) **v-SNAREs** See **SNAREs**.

Warburg effect Named after its discoverer, Otto Warburg, describes the observation that most cancer cells predominantly produce energy by glycolysis followed by fermentation of pyruvate to lactic acid. While normal cells use this form of energy production only under the oxygen-limiting (anaerobic) condition, cancer cells metabolize glucose in this manner even in the presence of sufficient oxygen. The process is thus also referred to as *aerobic glycolysis*.

Wee1 protein-tyrosine kinase; phosphorylates CDKs on threonine 14 and tyrosine 15 to inhibit CDK activity.

wild type Normal, nonmutant form of a gene, protein, cell, or organism.

Wnt A family of secreted signaling proteins used in the development of most tissues in most or all animals. Mutations in Wnt

signal transduction components are implicated in human cancer, especially colon cancer. Receptors are Frizzled-class proteins with seven transmembrane segments. (Figure 16-30)

x-ray crystallography Commonly used technique for determining the three-dimensional structure of macromolecules (particularly proteins and nucleic acids) by passing x-rays through a crystal of the purified molecules and analyzing the diffraction pattern of discrete spots that results. (Figure 3-43)

zinc finger Several related DNA-binding structural motifs composed of secondary structures folded around a zinc ion; present in numerous eukaryotic transcription factors. (Figures 3-9b and Figure 7-29a and b)

 Functional complementation
 defined, 189
 genomic library screening by, 188–191
 Functional protein domains, 67
 Fusion proteins, 326f

G

G protein-coupled receptors (GPCRs), 687–693
 adenylyl cyclase activation/inhibition,
 699–707
 defined, 674
 desensitization, 706f
 down-regulation by feedback repression, 706
 G protein activation by, 691–692
 in ion channel regulation, 693–699
 ligand-activated, 689–691, 690f
 mechanism, 689f
 olfactory, 1051f
 PAF binding to, 966
 pathways, 687
 signal transmission to MAP kinase, 742
 structure of, 687–688, 687f
 in triggering elevations in cytosolic Ca^{2+} ,
 707–713

G proteins
 activation, 690f, 691–692
 inhibitory, 692
 light activation of, 694–695
 monomeric, 377, 679
 opening K^+ channels, 693
 stimulatory, 692
 switching mechanism of, 679f
 trimeric, 378, 679, 692t

G_1 CDKs, 883
 G_1 cyclins, 885

G_2 phase, 15

G_1/S CDKs
 defined, 883
 phosphorylation, 894f

G_1/S cyclins, 885

G_1/S phase transition, 891f

G_2 phase, 15

G-actin. *See also* Actin; Actin filaments
 defined, 777
 monomers, 777
 polymerization in vitro, 780f
 structures of, 778f

Gain-of-function mutations, 1125–1126

GAL4 protein, 305–306

Gametes

 defined, 977
 fusion during fertilization, 980f

X-secretase-activating protein (GSAP), 762

Gap junctions, 934, 1023. *See also* Cell
 junctions

 connexins, 943–945
 electrical synapse dependence on, 1045
 illustrated, 944f
 metabolic coupling, 943
 in neuron communication, 1045–1046
 permeability, 945

$G_{\alpha s}$ -GTP, 700, 700f

Gated cation channels

 mechanoreceptors as, 1047–1048
 pain receptors as, 1048

Gel electrophoresis

 with autoradiography, 101
 defined, 94
 polyacrylamide (PAGE), 94
 SDS-polyacrylamide, 94–95, 95f
 two-dimensional, 95–96, 96f
 vector DNA separation, 191, 192f

Gel filtration chromatography, 97, 98f

Gels, protein detection in, 99

Gel-shift assays, 305

Gelsolin, 783

Gene control

 bacteria, 282–288
 components, 346
 eukaryotic, 288–295
 post-transcriptional, 335–393

Gene conversion, 159

Gene expression

 in bacteria, 281
 cloned DNA fragments in studying, 198–206
 heterochromatin and, 315
 microarrays and, 199–200
 regulation. *see* gene control
 steps in, 279
 transcription control of, 279–339

Gene families

 cytoskeleton, 229
 defined, 228
 recent evolution, 229

Gene function

 analytic tests based on, 180
 inactivating in eukaryotes, 212–218

Gene identification

 co-regulated, 200–201
 disease genes, 206–211
 by map position on chromosome, 180–182

Gene inactivation

 disruption construct in, 213–214, 214f
 RNA interference (RNAi) in, 216–218, 218f
 somatic cell recombination, 214–215
 wild-type GTPase, 217f

Gene knockout, 213–214

Gene position, analysis based on, 180

Gene therapy, 22

General import pore, 604

General transcription factors, 297–301

Genes, 212–213

 amplification, 1126
 apoptotic, 1143
 β -globin, 227, 228
 in cancer onset, 1127t
 caretaker, 1113, 1144–1150
 chromosomal organization, 231–234
 coding region, 9
 co-regulated, 200–201
 delayed-response, 892
 density, 231
 density comparison, 229f
 developmental regulation, 19
 duplication, 3, 226f, 228
 early-response, 741, 892
 economic clustering of, 127
 eukaryotic, 225–231
 haplo-insufficient, 173, 1128
 heat-shock, 325
 introns, 225
 multiple copies of, 229–230
 nonfunctional DNA between, 224
 nontranscribed, 260
 organization of, 126–128, 128f
 patterning, 19
 protein-coding, 1, 124–131, 185–186,
 227–229, 254–255
 regulatory region, 9
 reporter, 289
 structure overview, 224f
 tagging, 194–195, 204–205, 205f
 tumor-suppressor, 1113, 1128

 Genetic analysis

 cell cycle, 877–878, 878f

 mutations, 172–182

 Genetic code

 alterations in mitochondria, 249

 codons to amino acids, 132t

 defined, 131

 degenerate, 132

 mitochondrial, 249–250

 mRNA, 131–133

 as triplet code, 131

 universal, 133, 133f

Genetic complementation, 227

Genetic heterogeneity, 211

Genetic mapping

 gene identification based on, 180–181

 recombination during meiosis, 181f

 uses, 182

Genetic screens, 175

Genetic suppression

 interacting/redundant proteins and,
 179–180

 RNAi in, 436f

Genomes

 defined, 15, 60

 eukaryotic, 225–227

 nonfunctional DNA, 231–232

 number of protein-coding genes in, 254–255,
 255f

 organization, 223

 transposable DNA elements, 223–224

Genome-wide association study (GWAS), 211

Genomic libraries

 defined, 185

 yeast, 188–191, 191f

Genomics, 252–256

 defined, 225

 stored sequences, 252–253

Genotype, 172

Glial cells

 defined, 1019, 1023

 functions of, 1023–1024

 in myelin sheath production, 1033–1035

 types of, 1033–1035, 1034f

Glial fibrillary acidic protein (GFAP), 992

Glioblastomas, 1115

Gliomedin, 1035

Globular proteins, 64

Glucose

 anaerobic versus aerobic metabolism, 523f

 conversion to pyruvate, 520

 depletion, 283

 facilitated transport of, 478–480

 fermentation, 522–524

 mediated by GLUT proteins, 478f

 metabolism, 522, 522f, 523f

 transcellular transport of, 508–509, 508f

 transport into mammalian cells, 478–479

Glucose oxidation

 aerobic, summary, 527f

 citric acid cycle, 527–529

 electron transfer, 532–544

 glycolysis, 519–524

 harnessing protein-motive force, 544–552

 pyruvate conversion, 526–527

 stages, 520, 526

GLUT proteins, 479–480

GLUT1

 as catalyst, 478

 cellular uptake of glucose mediated by, 478f

 conformational states, 478

 defined, 478

 in erythrocyte membrane, 479

 uniport transport by, 478–479, 479f

 uniport transport model, 479f

GLUT2, 480, 509

GLUT3, 479

- GLUT4, 430, 480

 - symporters, 476, 502–508, 504f
 - uniporters, 476, 502
- Transposable DNA elements, 234–245
 - classes, 235f
 - defined, 234
 - Drosophila melanogaster*, 237
 - homologous recombination, 243
 - influence in evolution, 243–245
 - movement of, 235–236
- Transposition
 - by cut-and-paste mechanism, 237
 - defined, 234
 - exon shuffling via, 244f
 - in germ cells, 234
 - model of bacterial insertion sequences, 237f
 - in somatic cells, 235
- Transposons
 - defined, 235
 - eukaryotic, 236–238
 - illustrated, 235f
 - increased movement of, 373
 - mechanism, 237f
 - in prokaryotes, 236–238
 - unrelated flanking sequences, 244
- Trans-splicing, 355–356
- Treadmilling
 - actin filament, 782
 - defined, 781
 - illustrated, 781f
- Triacylglycerols, 41–42
- Triglycerides, 41–42, 530
- Trimeric G protein, 378, 679, 692r
- Triplet chlorophyll, 563
- Trypsin, 79f, 80–84, 81f
- Trithorax complexes
 - epigenetic control by, 330–331
 - opposing influence of, 332f
- trRNA (transfer RNA). *See also* RNAs (ribonucleic acid)
 - amino acid activation, 135
 - in bacterial cells, 133
 - cognate, 135
 - defined, 131
 - folded structures, 133–134
 - multiple copies of genes, 230
 - processing of, 384–392
 - role, 131f
 - structure of, 134f
- Trophoblast (TE), 979–981
- Tropoelastin, 960
- Tropomodulin, 802
- Tropomyosin, 803
- Troponin, 803
- Trp* operon, 286, 287f, 288
- TRPV1, 1048
- Tryptophan, 33, 35f
- T-SNAREs, 634, 639
- TTAGGG, 1148, 1149f
- Tubulin proteins
 - defined, 253, 822
 - drugs affecting polymerization, 829–830
 - in microtubule formation, 775
 - modifications, 842–843
 - post-translational modifications of, 843f
 - sequence generation, 254f
- Tumor cells, 1114–1124. *See also* Cancer
 - appearance, 1122
 - circulating, 1116
 - DNA microarray analysis, 1123–1124, 1124f
 - energy production in, 1123f
 - metastatic, as invasive, 1115–1116
 - normal cells versus, 1122–1123
 - systematic analysis of, 1119–1120
 - telomerase expression in immortalization, 1148–1149
 - telomerase production, 1149
- Tumor necrosis factor alpha (TNF α), 757, 1015
- Tumor necrosis factor (TNF), 1104
- Tumors
 - appearance kinetics, 1120f
 - carcinomas, 1115
 - cell growth into, 1114
 - formation by cancer stem cells, 1117
 - glioblastomas, 1115
 - gross and microscopic views, 1115f
 - growth requirement, 1117–1118
 - hypoxic, 1115
 - leukemias, 1115
 - lymphomas, 1115
 - malignant, 1115
 - microenvironment, 1117
 - oncogenic mutation, 1140
 - sarcomas, 1115
- Tumor-suppressor genes
 - apoptotic genes functioning as, 1143
 - defined, 1113
 - loss-of-function mutations in, 1128
- Turgor pressure, 481
- Two-dimensional gel electrophoresis, 95–96, 96f
- Type I proteins, 588–589, 588f
- Type II proteins, 589–590, 589f
- Type III proteins, 589–590, 589f
- Type IV collagen
 - assembly of, 950f
 - in basal lamina, 947–950
 - defined, 947
 - structure of, 950f
- Type IV proteins, 591–592
- Tyrosine, 33, 35f
- Tyrosine kinases
 - ligands for, 723–724
 - receptors activating, 723–734
- U**
- Ubiquitin
 - defined, 87
 - functions of, 87–88
 - in protein degradation, 87–88
 - proteolysis, 86f
- Ubiquitination
 - monoubiquitination, 90
 - multiubiquitination, 90
 - polyubiquitination, 90–91
 - process, 87
 - in protein regulation, 90–91
- Ubiquitin-binding domains (UBD), 91
- Umami taste, 1050
- Unclassified spacer DNA, 233–234
- Unfolded-protein response, 600f
- Uniport membrane transport
 - defined, 477–478
 - diffusion versus, 478
 - by GLUT1, 478–479, 479f
- Uniporters
 - cotransporters versus, 502
 - defined, 476
- Unsaturated fatty acids, 40, 42, 465
- Untranslated regions (UTRs), 129, 375f
- Upstream activating sequences (UASs), 304, 305
- Upstream transcription, 289
- Uptake-targeting sequences
 - defined, 579
 - directing proteins from cytosol to organelles, 602f
- Urbilateria, 19
- V**
- Vaccines, 1105–1107
- Vacuoles
 - contractile, 481
 - metabolites and ions accumulation, 507, 507f
- Valine, 33
- VAMP (vesicle-associated membrane protein), 639
- Van der Waals interactions
 - defined, 30
 - oxygen molecules in, 30f
 - by transient dipoles, 30–31
- Vascular endothelial growth factor (VEGF), 1117
- V-class H⁺ pumps, 490–491, 490f
- V-class ion pumps, 484, 484f
- Vectors
 - Escherichia coli*, 184–185
 - expression, 203–205
 - gel electrophoresis and, 191, 192f
 - inserting DNA fragments into, 183
 - plasmid, 203
 - plasmid cloning, 185f
 - retroviral, 205f
 - shuttle, 188–191, 190f
- Vesicle budding
 - defined, 635
 - molecular mechanism, 634–640
 - overview, 634f
 - scheme, 635
 - from TGN, 647
 - visualization, 635f
- Vesicle fusion
 - by ATP hydrolysis, 639–640
 - molecular mechanism, 634–640
 - SNARE proteins, 639–640
 - with target membranes, 639
- Vesicles
 - autophagic, 665
 - clathrin, 634, 647–648
 - coated, 634–637
 - COPI, 634, 635, 642–643
 - COPII, 634, 636f, 640–642
 - endocytic, 776
 - myosin-V-bound, 805–808
 - secretory, 651
 - synaptic, 1022, 1037f, 1038–1040
- Vesicular glutamate transporters (VGLUTs), 1039
- Vesicular stomatitis virus (VSV), 633, 633f
- Vesicular transport
 - anterograde, 643–645
 - cell-free assays, 633, 633f
 - COPI, 642–643
 - COPII, 640–642
 - docking and fusion model, 638f
 - retrograde, 642–643
 - sorting signals, 637r
 - trans-Golgi network (TGN), 646f
 - vesicle buds and, 636–637
 - yeast mutants, 632, 632f
- Vestibules, 498
- Vesicular stomatitis virus, 21
- Vibrio cholera*, 692

Virions, 163
 defined, 160
 progeny, 164f
 structure of, 161
 Virus associated RNA (VA RNA), 379
 Viruses, 160–166
 adenoviruses, 21
 animal, 160, 162
 cancer-causing, 1127–1128
 clone, 160
 as experimental organism, 12f
 host range, 160
 lytic cycle, 161–162, 162f, 163f
 in molecular cell biology research, 21–22
 nucleocapsids, 160
 phage, 160
 plant, 160, 162
 prophage, 164
 replication of, 1061
 retroviruses, 164, 165f
 structures, 116, 161
 vesicular stomatitis, 21
 Visual adaptation, 698
 Visual cortex, 1047
 Voltage-gated channels
 defined, 1025
 K^+ , 1027–1028, 1027f
 Na^+ , 1026–1027, 1026f, 1028f
 secondary structures, 1030f
 sequential opening/closing of, 1025–1029
 structure of, 1029–1030
 V-SNAREs, 634, 639
 VSVG-GFP, 631, 632

W

Wall-associated kinases (WAKs), 970–971
 Warburg effect, 1122
 Water

facilitated transport of, 480–483
 hydrogen bonds of, 29f
 molecule, dipole nature of, 27f
 osmotic pressure in movement of, 480–481
 Watson, James D., 7, 7f
 Watson-Crick base pairs, 118–119
 Weak promoters, 284
 Wee1, 898
 White-fat tissue, 551
 Wild typed, 172
 Wnt signaling
 binding to receptors, 752
 from *Drosophila sugarless (sgl)* mutants, 753
 inappropriate pathway activation, 753
 pathway, 753f
 pathway activation, 752
 transcription factor release, 752–753
 Wobble position, 134, 135f
 Wounded-cell monolayer assay, 813f

X

X chromosomes
 inactivation, 262–263
 inactivation in mammals, 332–333, 332f
Xenopus laevis
 cell cycle study, 877
 early embryos, 878–880
 in mitosis study, 880
 oocytes, 878–880, 880f
 X-linked recessive allele, 206–207, 207t
 X-ray crystallography, 104–105, 105f

Y

Yeasts. *See also Saccharomyces cerevisiae*
 asymmetric growth during mating, 998
 autonomously replicating sequences (ARSs), 270, 271f

budding, 877–878, 878f
 cargo movement by myosin Vs in, 806f
 disruption of, 213
 essential genes, study of, 175–176
 as experimental organism, 12f
 fission, 877–878, 879f
 genomic libraries, 188–191, 191f
 Golgi apparatus, 16
 growth, 17
 haploid, switching of mating type in, 382f
 human mediator complexes and, 321f
 MAP kinase cascades, 743f
 mRNP particle transport, 383f
 mutant allele replacement, 212–213
 mutants, 632, 632f
 nuclear RNA polymerase, 293
 pheromone-induced mating, 742f
 sexual cycle, 17
 shmoo formation in, 999f
 SR protein, 367
 telomeric heterochromatin in, 317f
 transfection experiments, 271
 two-hybrid system, 321–322, 323f
 Ty element, 240f

Z

Zebrafish
 as experimental organism, 12f
 muscle/nerve development, 19
 Zellweger syndrome, 613
 Zinc finger
 defined, 309
 proteins, 309–311
 secondary structures, 66
 structure types, 309
 Zwitterions, 46–47
 Zymogens, 92

Enjoy the version of this book and also the photo!!!
